Hepatitis B—A virus that is spread through blood and sexual contact and causes hepatitis. Hepatitis causes the liver to inflame and can cause liver cancer.

Human papillomavirus (HPV)—A virus that causes abnormal tissue growth. Certain types of HPV can cause cervical and other types of cancer such as anal and vaginal cancer.

Looking at cancer vaccines overall, this treatment method has been more successful eliminating very small tumors rather than getting rid of a large tumor load. If the size of the tumor is significant, a more realistic goal is to shrink the tumor and reduce its effect on the patient's body, rather than total elimination of the cancer.

The complexity of the human immune system has made it very difficult to develop an effective vaccine. Tumors have strategies to evade detection by the immune system. Most notably, they mimic the outward appearance and antigens of the body's own cells. The immune system's built-in lack of response against "self" allows the tumor to escape notice by the body. Now fully aware of this phenomenon, researchers are working to develop methods of circumventing this problem to develop a highly effective vaccine system.

There has been a huge success with preventative cancer vaccines. A vaccine introduced in 2006 protects against four HPV viruses that cause 70% of cervical cancers and 90% of **genital warts**. The vaccine is most effective when given before a female becomes sexually active. It is recommended for all women ages 11–18 and may be given as young as age nine. Women ages 19–26 also may be vaccinated at the discretion of their physician. The vaccine is given in three doses over a six-month period and is covered by most health insurance programs.

Universal childhood **vaccination** against hepatitis B has been practiced in the United States since 1991. Hepatitis B vaccine usually is the first vaccine a child receives, most often while still in the hospital within 24 hours after birth. The second and third HBV immunizations are administered by the age of 18 months in conjunction with other routine childhood vaccinations.

The Centers for Disease Control and Prevention (CDC) estimates that before the launch of the infant HBV immunization program, about 33,000 American children of non-infected mothers acquired hepatitis B by the age of ten. This number has substantially decreased. In 2007, 4,519 cases of acute Hepatitis B in the United States were reported, the lowest ever recorded. However, this number is thought to be about a ten-fold underestimate because many new cases do not cause symptoms and are not reported.

Preparation

Before enrolling in a clinical trial, patients should discuss the potential benefits and risks with their doctor. Clinical trials can be located by contacting the research institutes directly or by searching the Internet. The National Cancer Institute is a good resource for information about clinical trials for cancer treatment. Patients should talk to their doctor about receiving preventative cancer vaccines.

Aftercare

One of the most striking advantages of vaccines compared to other cancer treatments is the relatively low incidence of side effects. If IFN is used as an immunoadjuvant, patients sometimes experience flu-like symptoms. However, other than some soreness at the site of injection, vaccine patients generally have no adverse reactions to this kind of treatment.

WWW.BOOKBAZ.IR

It is possible to have an allergic reaction to the HPV or hepatitis B vaccine or to experience some swelling or soreness around the injection site. Patients should contact their doctor if they have any unusual reactions to the vaccines.

Results

For each trial, a very small percentage of patients have complete, partial, or mixed response to experimental cancer treatment vaccines. A few others show a stabilization of the disease where deterioration of the condition would be expected. As traditional treatments were often unsuccessful with these patients, these results are significant. However, the very low rate of success underscores the complexity of the human immune system, the number of variables in the vaccine method, and the amount of research necessary to develop an effective vaccine treatment for this disease.

Candida albicans infection *see* **Candidiasis**

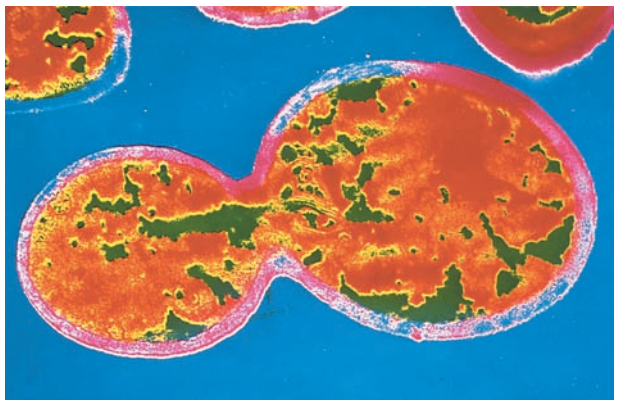
Candidiasis

Definition

Candidiasis is an infection caused by a species of the yeast *Candida*, usually *Candida albicans*. This is a common cause of vaginal infections in women. Also, *Candida* may cause mouth infections in people with reduced immune function, or in patients taking certain **antibiotics**. *Candida* can be found in virtually all normal people but causes problems in only a fraction. In recent years, however, several serious categories of candidiasis have become more common, due to overuse of antibiotics, the rise of **AIDS**, the increase in organ transplantations, and the use of invasive devices (catheters, artificial joints, and valves)—all of which increase a patient's susceptibility to infection.

Demographics

The candida organism is present in the oropharyngeal areas in 30 to 55% of healthy young adults.



A transmission electron microscopy (TEM) of *Candida albicans*. *(Custom Medical Stock Photo, Inc.)*

About 75% of women are infected with vaginal candidiasis at least one time in their lifetime. The candida species is now the fourth most commonly isolated organism from blood cultures and is the most common cause of fungal infection in patients whose immune systems are compromised.

Risk factors

Patients at high risk for the development of candidiasis include patients who are often extremely ill. Patients in neonatal, pediatric, and adult intensive care units are considered to be at high risk. Other high risk patients are patients who are immunosuppressed due to **chemotherapy**, **radiation therapy**, severe **trauma**, and organ transplantation. Patients undergoing procedures such as recent surgery, hemodialysis, **urinary catheterization**, central **venous access** device placement, and those on mechanical ventilation for longer than 3 days are at high risk for the development of invasive or systemic candidiasis.

Neonates and older adults over the age of 65 years are at highest risk for infection with the candida organism.

Description

Vaginal candidiasis

Over one million women in the United States develop vaginal yeast infections each year. It is not life-threatening, but it can be uncomfortable and frustrating.

Oral candidiasis

This disorder, also known as thrush, causes white, curd-like patches in the mouth or throat.

Deep organ candidiasis

Also known as invasive candidiasis, deep organ candidiasis is a serious systemic infection that can affect the esophagus, heart, blood, liver, spleen, kidneys, eyes, and skin. Like vaginal and oral candidiasis, it is an opportunistic disease that strikes when a person's resistance is lowered, often due to another illness. There are many diagnostic categories of deep organ candidiasis, depending on the tissues involved.

Causes and symptoms

Vaginal candidiasis

Most women with vaginal candidiasis experience severe vaginal **itching**. They also have a discharge that often looks like cottage cheese and has a sweet or bread-like odor. The vulva and vagina can be red, swollen, and painful. Sexual intercourse can also be painful.

Oral candidiasis

Whitish patches can appear on the tongue, inside of the cheeks, or the palate. Oral candidiasis typically occurs in people with abnormal immune systems. These can include people undergoing chemotherapy for cancer, people taking immunosuppressive drugs to protect transplanted organs, or people with HIV infection.

Deep organ candidiasis

Anything that weakens the body's natural barrier against colonizing organisms—including stomach surgery, **burns**, nasogastric tubes, and catheters—can predispose a person for deep organ candidiasis. Rising numbers of AIDS patients, organ transplant recipients, and other individuals whose immune systems are compromised help account for the dramatic increase in deep organ candidiasis in recent years. Patients with granulocytopenia (deficiency of white blood cells) are particularly at risk for deep organ candidiasis.

Diagnosis

Often clinical appearance gives a strong suggestion about the diagnosis. Generally, a clinician will take a sample of the vaginal discharge or swab an area of oral plaque, and then inspect this material under a microscope. Under the microscope, it is possible to see characteristic forms of yeasts at various stages in the lifecycle.

Fungal blood cultures should be taken for patients suspected of having deep organ candidiasis.

WWW.BOOKBAZ.IR

This patient's tongue is infected with candidiasis. *(Custom Medical Stock Photo, Inc.)*

However, blood cultures may not detect up to 50% of cases of disseminated candidiasis. A more specific test to detect Beta-glucan, a fungal cell wall component, is the serum Beta-D-glucan detection assay. This test has shown to be highly specific in detecting **fungal infections**.

A tissue biopsy of suspected infected areas may also be helpful in confirming a diagnosis of systemic or disseminated candidiasis.

Treatment

Vaginal candidiasis

In most cases, vaginal candidiasis can be treated successfully with a variety of over-the-counter antifungal creams or suppositories. These include Monistat, Gyne-Lotrimin, and Mycelex. However, infections often recur. However, a single 150 mg dose of oral fluconazole (Diflucan) has been shown to as effective or better than topical antifungal agents when treating acute cases of vaginal candidiasis.

Oral candidiasis

This is usually treated with prescription lozenges or mouthwashes. Some of the most-used prescriptions are nystatin mouthwashes (Nilstat or Nitrostat) and clotrimazole lozenges. Other treatment options include amphotericin B oral suspension or treatment with systemic azole medications such as fluconazole (Diflucan), itraconazole (Sporonox), or posaconazole (Noxafil) for more severe oral infections.

Deep organ candidiasis

Guidelines for the treatment of invasive candidiasis were revised in 2009 by the Infectious Diseases Society of America (ISDA). The guidelines include the recommended use of drugs such as caspofungin (Cancidas), micafungin (Mycamine), and anidulafungin (Eraxis), which are classified as echinocandins, and the drugs voriconazole (Vfend) and posaconazole (Noxafil), which are classified as triazoles. Lipid formulations of amphotericin B are also recommended in the treatment of systemic fungal infections caused by candida organisms. Treatment with fluconazole (Diflucan) continues to be recommended as first line treatment for invasive candidiasis in non-neutropenic patients.

Alternatives

Home remedies for vaginal candidiasis include vinegar douches or insertion of a paste made from *Lactobacillus acidophilus* powder into the vagina. In theory, these remedies will make the vagina more acidic and therefore less hospitable to the growth of *Candida*. Fresh garlic (*Allium sativum*) is believed to have antifungal action, so incorporating it into the diet or inserting a gauze-wrapped, peeled garlic clove into the vagina may be helpful. The insert should be changed twice daily. Some women report success with these remedies; they should try a conventional treatment if an alternative remedy is not effective.

KEY TERMS

Biopsy—The removal and examination of tissue from a live body.

Colonize—To become established in a host.

Granulocytopenia—A condition characterized by a deficiency of white blood cells.

Nasogastric—Tube inserted through the nasal passages into the stomach.

Opportunistic—Infection caused by microorganisms that are usually harmless, but which can cause disease when a host's resistance is lowered.

Systemic—Afflicting an entire body system or the body in general.

RACHEL FULLER BROWN (1898–1980)

Rachel Fuller Brown was born on November 23, 1898 in Springfield, Massachusetts. Brown was the oldest of two children born to Annie (Fuller) and George Hamilton Brown. In 1912, her father left their family in Missouri and her mother moved the family back to Springfield. Brown double-majored in history and chemistry at Mount Holyoke, receiving her A.B. degree in 1920. She also earned her M.A. degree from the University of Chicago. Brown began her doctoral studies at the University, but she experienced financial difficulties and took a job before she received her Ph.D. She worked at the Division of Laboratories and Research of the New York State Department of Health as an assistant chemist for seven years and finally returned to Chicago and completed her Ph.D.

In 1948, Brown and Elizabeth Hazen began researching fungal infections found in humans due to antibiotic treatments and diseases. Some of the antibiotics they discovered did indeed kill the fungus; however, they also killed the test mice. Finally, Hazen located a microorganism on a farm in Virginia, and Brown's tests indicated that the microorganism produced two antibiotics, one of which proved effective for treating fungus and candidiasis in humans. Brown purified the antibiotic which was patented under the name *nystatin*. In 1954, the antibiotic became available in pill form. Brown and Hazen continued their research and discovered two other antibiotics. Brown received numerous awards individually and with her research partner, Elizabeth Hazen. Rachel Brown died on January 14, 1980.

Prognosis

Vaginal candidiasis

Although most cases of vaginal candidiasis are cured reliably, these infections can recur. To limit recurrences, women may need to take a prescription anti-fungal drug or take other anti-fungal drugs on a preventive basis.

Oral candidiasis

These infections can also recur, sometimes because the infecting *Candida* develops resistance to one drug. Therefore, a physician may need to prescribe a different drug.

Deep organ candidiasis

The prognosis depends on the category of disease as well as on the condition of the patient when the infection strikes. Patients who are already suffering from a serious underlying disease are more susceptible to deep organ candidiasis that spreads throughout the body.

Mortality rates for disseminated candidiasis have not improved significantly over the years. It is estimated that as many as 30 to 40% of patients diagnosed with severe cases of systemic candidiasis will die from infection with this pathogen.

Prevention

Because *Candida* is part of the normal group of microorganisms that co-exist with all people, it is impossible to avoid contact with it. Good vaginal hygiene and good **oral hygiene** might reduce problems, but they are not guarantees against candidiasis.

Because hospital-acquired (nosocomial) deep organ candidiasis is on the rise, people need to be made aware of it. Patients should be sure that catheters and other medical devices are properly maintained and used for the shortest possible time lengths.

Canker sores

Definition

Canker sores are small white or yellowish sores or **ulcers** that develop inside the mouth. They are painful, self-healing, and can recur.

Description

Canker sores occur on the inside of the mouth, usually on the inside of the lips, cheeks, and/or soft palate. They also can occur on the tongue and in the throat. Often, several canker sores will appear at the same time and may be grouped in clusters. Canker sores appear as a whitish, round area with a red border. The sores are painful and sensitive to touch. The average canker sore is about .25 inch (60 mm) in diameter, although they can occasionally be larger. Canker sores are not infectious.

Approximately 20% of Americans experience recurring canker sores. They are more common in women than in men. Women are more likely to have canker sores at certain times during their menstrual period, suggesting that they may be influenced by female hormones.

Canker sores are sometimes confused with **cold sores**. Cold sores are caused by herpes simplex virus. This disease, also known as oral herpes or fever blisters, can occur anywhere on the body. Most commonly, herpes infection occurs on the outside of the lips and the gums, and much less frequently on the inside the mouth. Unlike canker sores, cold sores are infectious.

Causes and symptoms

The exact cause of canker sores is uncertain; however, they seem to be related to a localized immune reaction. Other proposed causes for this disease are **trauma** to the affected areas from toothbrush scrapes or dental cleanings, **stress**, hormones, and **food allergies**. They may also be related to nutritional deficiencies.

Canker sores commonly tend to appear in response to stress. The initial symptom is a tingling or mildly painful, **itching** sensation in the area where the sore will appear. After one to three days, a small red swelling appears. The sore is round and whitish in color with a grayish colored center. Usually, there is a red ring of inflammation surrounding the sore. The main symptom is **pain**. Canker sores can be very painful, especially if the tongue touches them repeatedly. They last for one to two weeks and heal on their own.

KEY TERMS

Inflammation—A local reaction to tissue injury or damage, usually characterized by pain, swelling, and redness.

Ulcer—A site of damage to the skin or mucous membrane that is characterized by the formation of pus, death of tissue, and is frequently accompanied by an inflammatory reaction.

Diagnosis

Canker sores are diagnosed by observation of the blister. A distinction between canker sores and cold sores must be made because cold sores are infectious, and herpes infection can be transmitted to other people. The two sores can usually be distinguished visually, and there are specific diagnostic tests for herpes infection.

Treatment

Since canker sores heal by themselves, treatment is not usually necessary. Pain relief remedies, such as over-the-counter topical anesthetics, may be used to reduce the pain of the sores. The use of corticosteroid ointments sometimes speeds healing. Avoidance of spicy or acidic foods can help reduce the pain associated with canker sores.

Alternatives

Alternative therapies for canker sores are aimed at healing existing sores and preventing their recurrence. Several herbal remedies, including calendula (*Calendula officinalis*), myrrh (*Commiphora molmol*), and goldenseal (*Hydrastis canadensis*), may be helpful in the treatment of existing sores. Compresses soaked in teas made from these herbs are applied directly to the sores. The tannic acid in a tea bag can also help dry up the sores when the wet tea bag is used as a compress. Taking dandelion (*Taraxacum officinale*) tea or capsules may help heal sores and prevent future outbreaks. Since canker sores are often brought on by stress, such stress-relieving techniques as **meditation**, **guided imagery**, and certain **acupressure** exercises may help prevent canker sores or lessen their severity.

Prognosis

There is no cure for canker sores. They do not get larger or occur more frequently with age.

Carbohydrate intolerance

Definition

Carbohydrate intolerance is the inability of the body to completely process carbohydrates (a classification that includes sugars and starches) into a source of energy for the body, usually because of the deficiency of an enzyme needed for digestion.

Demographics

The rate of **lactose intolerance**, the inability to digest the sugar found in milk, is widespread and varies with ethnicity. About 25% of white Americans are thought to be lactose intolerant, of which half are thought to lack the enzyme lactase needed to digest lactose. The rate is lowest in people of Northern European ancestry (about 5%) increasing to 30% of Central Europeans and 70% of Southern Europeans. About 90% of Asians and Africans are lactose intolerant. Often intolerance increases as the individual moves from infancy through childhood and into adulthood. In addition, according to a poll done for the pharmaceutical company GlaxoSmithKline, about 30% of Americans show symptoms of complex carbohydrate intolerance.

Description

Carbohydrates are the primary source of energy for the body and, along with fats and proteins, one of the three major nutrients in the human diet. Carbohydrates are classified according to their structure based on the number of basic sugar (saccharide) units they contain.

A monosaccharide is the simplest carbohydrate and is called a simple sugar. Simple sugars include glucose (the form in which sugar circulates in the blood), fructose (found in fruit and honey), and galactose (produced by the digestion of milk). These simple sugars are important because they can be absorbed by the small intestine.

Two simple sugars linked together make a disaccharide. The disaccharide sugars present in the diet are maltose (a product of the digestion of starch), sucrose (table sugar), and lactose (the sugar in milk). These disaccharides must be broken down by enzymes into two simple sugars in order for them to be absorbed by the intestine. Polysaccharides are much more complex carbohydrates made up of many simple sugars, the most important of which are glycogen, which is stored in the liver, and starch.

Digestion of sugars

Digestion of food begins in the mouth, moves on to the stomach, and then into the small intestine. Along the way, specific enzymes are needed to process different types of sugars. An enzyme is a substance that acts as a catalyst to produce chemical changes without being changed itself. The enzymes lactase, maltase, and isomaltase (or sucrase) are needed to break down the disaccharides; when one or more enzymes is produced in inadequate amounts, the result is carbohydrate intolerance. Adult lactose intolerance is the most common of all enzyme deficiencies. Deficiencies in enzymes other than lactase are extremely rare.

Types of intolerance

Carbohydrate intolerance can be primary or secondary. Primary deficiency is caused by an enzyme defect present at birth or developed over time. The most common carbohydrate intolerance is lactose intolerance. Secondary deficiencies are caused by a disease or disorder of the intestinal tract; they disappear when the disease is treated. These include protein deficiency, **celiac disease**, and some intestinal infections.

Causes and symptoms

Enzymes play an important role in breaking down carbohydrates into forms that can pass through the intestine and be used by the body. Cooked starch is broken down in the mouth to a disaccharide by amylase, an enzyme in the saliva. The disaccharides

WWW.BOOKBAZ.IR

KEY TERMS

Celiac disease—A disease, occurring in both children and adults, which is caused by a sensitivity to gluten, a protein found in grains. It results in chronic inflammation and shrinkage of the lining of the small intestine.

Digestion—The mechanical, chemical, and enzymatic process in which food is converted into the materials suitable for use by the body.

Enzyme—A substance produced by the body to assist in a chemical reaction. In carbohydrate intolerance, lack of an enzyme makes it impossible for one type of sugar to be broken down into a simpler form so that it can be absorbed by the intestines and used by the body.

Lactase—The enzyme needed to break down lactose, the sugar found in milk.

Metabolism—All the physical and chemical changes that take place within an organism.

Nutrient—Food or another substance that supplies the body with the elements needed for metabolism.

Sugars—Carbohydrates having the general composition of one part carbon, two parts hydrogen, and one part oxygen.

maltose, sucrose, and lactose cannot be absorbed until they have been separated into simple sugar molecules by their corresponding enzymes present in the cells lining the intestinal tract. If this process is not completed, digestion is interrupted.

Although not common, a deficiency in the enzymes needed to digest lactose, maltose, and sucrose is sometimes present at birth. Intestinal lactase enzymes usually decrease naturally with age, but this happens to varying degrees. Because of the uneven distribution of enzyme deficiency based on race and ethnic heritage, especially in lactose intolerance, genetics are believed to play a role in the cause of primary carbohydrate intolerance.

Digestive diseases such as celiac disease and tropical sprue (which affect absorption in the intestine), as well as intestinal infections and injuries, can reduce the amount of enzymes produced. In cancer patients, for example, treatment with **radiation therapy** or **chemotherapy** may affect the cells in the intestine that normally secrete lactase, leading to secondary carbohydrate intolerance.

The severity of the symptoms depends on the extent of the enzyme deficiency, and range from a feeling of mild bloating to severe **diarrhea**. In the case of a lactase deficiency, undigested milk sugar remains in the intestine, where bacteria normally present in the intestine then ferment it. These bacteria produce gas, cramping, bloating, or a "gurgly" feeling in the abdomen. In a growing child, the main symptoms are diarrhea and a failure to gain weight. In an individual with lactase deficiency, gastrointestinal distress begins about 30 minutes to two hours after eating or drinking foods containing lactose. Food intolerances should not be confused with **food allergies**, which cause a biochemical allergic response in the body, but the symptoms of nausea, cramps, bloating, and diarrhea can be similar.

Sugars that are not broken down into one of the simplest forms cause the body to push fluid into the intestines, which results in watery diarrhea (osmotic diarrhea). Diarrhea may sweep other nutrients out of the intestine before they can be absorbed, causing **malnutrition**.

Diagnosis

Tests

Carbohydrate intolerance can be diagnosed using oral tolerance tests. The carbohydrate being investigated is given by mouth in liquid form and several blood levels are measured and compared to normal values. This helps evaluate the individual's ability to digest the sugar.

To identify lactose intolerance in children and adults, the hydrogen breath test is used to measure the amount of hydrogen in the breath. The patient drinks a beverage containing lactose and the breath is analyzed at regular intervals. If undigested lactose in the large intestine (colon) is fermented by bacteria, various gases are produced. Hydrogen is absorbed from the intestines and carried by the bloodstream into the lungs where it is exhaled. Normally there is very little hydrogen detectable in the breath, so its presence indicates faulty digestion of lactose.

When lactose intolerance is suspected in infants and young children, many pediatricians recommend simply changing from cow's milk to soy formula and watching for improvement. If needed, a stool sample can be tested for acidity. The inadequate digestion of lactose will

result in an increase of acid in the waste matter excreted by the bowels and the presence of glucose.

Treatment

Carbohydrate intolerance caused by temporary intestinal diseases disappears when the condition is successfully treated. In primary conditions, no treatment exists to improve the body's ability to produce the enzymes, but symptoms can be controlled by diet.

For those individuals who are sensitive to even very small amounts of lactose, the lactase enzyme is available without a prescription. It comes in liquid form for use with milk. The addition of a few drops to a quart of milk will reduce the lactose content by 70% after 24 hours in the refrigerator. Heating the milk speeds up the process, and doubling the amount of lactase liquid will result in milk that is 90% lactose free. Chewable lactase enzyme tablets are also available. Three to six tablets taken before a meal or snack will aid in the digestion of solid foods. Lactose-reduced milk and other products are also available in stores. The milk contains the same nutrients as regular milk.

Because the degree of lactose intolerance varies so much, treatment should be tailored for the individual. Young children showing signs of intolerance should avoid milk products; infants should switch to soy-based formula. Older children and adults can adjust their intake of lactose depending on how much and what they can tolerate. For some, a small glass of milk will not cause problems, while others may be able to handle ice cream or aged cheeses such as cheddar or Swiss, but not other dairy products. Generally, small amounts of lactose-containing foods taken throughout the day are better tolerated than a large amount consumed all at once.

Because dairy products are an important source of **calcium**, people who reduce or severely limit their intake of dairy products may need to consider other ways to consume an adequate amount of calcium in their **diets**.

Prognosis

With good dietary management, individuals with carbohydrate intolerance can lead normal lives with minimal discomfort.

Prevention

Since the cause of the enzyme deficiency leading to carbohydrate intolerance is unknown, there is no way to prevent this condition.

Carbon monoxide poisoning

Definition

Carbon monoxide (CO) **poisoning** occurs when carbon monoxide gas is inhaled. CO is a colorless, odorless, highly poisonous gas that is produced by incomplete combustion. It is found in automobile exhaust fumes, faulty stoves and heating systems, fires, and cigarette smoke. Other sources include wood-burning stoves, kerosene heaters, improperly ventilated water heaters and gas stoves, and blocked or poorly maintained chimney flues. CO interferes with the ability of the blood to carry oxygen. The result is **headache**, nausea, convulsions, and finally death by asphyxiation.

Description

Carbon monoxide, sometimes called coal gas, has been known as a toxic substance since the third century B.C. It was used for executions and suicides in early Rome. In 2014 it is the leading cause of accidental poisoning in the United States. According to the *Journal of the American Medical Association*, 2,000 Americans die each year from accidental exposure to CO, and another 2,300 from intentional exposure (**suicide**). An additional 10,000 people seek medical attention after exposure to CO. The Consumer Products Safety Commission reported in 2004 that about 64% of unintentional CO poisoning deaths occur in the home.

WWW.BOOKBAZ.IR

Anyone who is exposed to CO will become sick, and the entire body is involved in CO poisoning. A developing fetus can also be poisoned if a pregnant woman breathes CO gas. Infants, people with heart or lung disease, or those with anemia may be more seriously affected. People such as underground parking garage attendants who are exposed to car exhausts in a confined area are more likely to be poisoned by CO. Firemen also run a higher risk of inhaling CO.

Causes and symptoms

Normally when a person breathes fresh air into the lungs, the oxygen in the air binds with a molecule called hemoglobin (Hb) that is found in red blood cells. This allows oxygen to be moved from the lungs to every part of the body. When the oxygen/hemoglobin complex reaches a muscle where it is needed, the oxygen is released. Because the oxygen binding process is reversible, hemoglobin can be used over and over again to pick up oxygen and move it throughout the body.

Inhaling carbon monoxide gas interferes with this oxygen transport system. In the lungs, CO competes with oxygen to bind with the hemoglobin molecule. Hemoglobin prefers CO to oxygen and accepts it more than 200 times more readily than it accepts oxygen. Not only does the hemoglobin prefer CO, it holds on to the CO much more tightly, forming a complex called carboxyhemoglobin (COHb). As a person breathes CO contaminated air, more and more oxygen transportation sites on the hemoglobin molecules become blocked by CO. Gradually, there are fewer and fewer sites available for oxygen. All cells need oxygen to live. When they don't get enough oxygen, cellular metabolism is disrupted and eventually cells begin to die.

The symptoms of CO poisoning and the speed with which they appear depend on the concentration of CO in the air and the rate and efficiency with which a person breathes. Heavy smokers can start off with up to 9% of their hemoglobin already bound to CO, which they regularly inhale in cigarette smoke. This makes them much more susceptible to environmental CO. The Occupational Safety and Health Administration (OSHA) has established a maximum permissible exposure level of 50 parts per million (ppm) over eight hours.

With exposure to 200 ppm for two to three hours, a person begins to experience headache, **fatigue**, nausea, and **dizziness**. These symptoms correspond to 15–25% COHb in the blood. When the concentration of COHb reaches 50% or more, death results in a very short time. Emergency room physicians have the most experience diagnosing and treating CO poisoning.

The symptoms of CO poisoning in order of increasing severity include:

- headache
- shortness of breath
- dizziness
- fatigue
- mental confusion and difficulty thinking
- loss of fine hand-eye coordination
- nausea and vomiting
- rapid heart rate
- hallucinations
- inability to execute voluntary movements accurately
- collapse
- lowered body temperature (hypothermia)
- coma
- convulsions
- seriously low blood pressure
- cardiac and respiratory failure
- death

In some cases, the skin, mucous membranes, and nails of a person with CO poisoning are cherry red or bright pink. Because the color change doesn't always occur, it is an unreliable symptom to rely on for diagnosis.

Although most CO poisoning is acute, or sudden, it is possible to suffer from chronic CO poisoning. This condition exists when a person is exposed to low levels of the gas over a period of days to months. Symptoms are often vague and include (in order of frequency) fatigue, headache, dizziness, sleep disturbances, cardiac symptoms, apathy, nausea, and memory disturbances. Little is known about chronic CO poisoning, and it is often misdiagnosed.

Diagnosis

The main reason to suspect CO poisoning is evidence that fuel is being burned in a confined area, for example a car running inside a closed garage, a charcoal grill burning indoors, or an unvented kerosene heater in a workshop. Under these circumstances, one or more persons suffering from the symptoms listed previously strongly suggests CO poisoning. In the absence of some concrete reason to suspect CO poisoning, the disorder is often misdiagnosed as **migraine headache**, **stroke**, psychiatric illness, **food poisoning**, alcohol poisoning, or **heart disease**.

KEY TERMS

Carboxyhemoglobin (COHb)—Hemoglobin that is bound to carbon monoxide instead of oxygen.

Hemoglobin (Hb)—A molecule that normally binds to oxygen in order to carry it to our cells, where it is required for life.

Hypothermia—Development of a subnormal body temperature.

pH—A measurement of the acidity or alkalinity of a fluid. A neutral fluid, neither acid nor alkali, has a pH of 7.

Concrete confirmation of CO poisoning comes from a carboxyhemoglobin test. This blood test measures the amount of CO that is bound to hemoglobin in the body. Blood is drawn as soon after suspected exposure to CO as possible.

Other tests that are useful in determining the extent of CO poisoning include measurement of other arterial blood gases and pH; a **complete blood count**; measurement of other blood components such as **sodium**, potassium, bicarbonate, urea nitrogen, and lactic acid; an electrocardiogram (ECG); and a chest x ray.

Treatment

Immediate treatment for CO poisoning is to remove the victim from the source of carbon monoxide gas and get him or her into fresh air. If the victim is not breathing and has no pulse, **cardiopulmonary resuscitation** (CPR) should be started. Depending on the severity of the poisoning, 100% oxygen may be given with a tight fitting mask as soon as it is available.

Taken with other symptoms of CO poisoning, COHb levels of over 25% in healthy individuals, over 15% in patients with a history of heart or lung disease, and over 10% in pregnant women usually indicate the need for hospitalization. In the hospital, fluids and electrolytes are given to correct any imbalances that have arisen from the breakdown of cellular metabolism.

In severe cases of CO poisoning, patients are given **hyperbaric oxygen therapy**. This treatment involves placing the patient in a chamber breathing 100% oxygen at a pressure of more than one atmosphere (the normal pressure the atmosphere exerts at sea level). The increased pressure forces more oxygen into the blood. Hyperbaric facilities are specialized, and are usually available only at larger hospitals.

Prognosis

The speed and degree of recovery from CO poisoning depends on the length and duration of exposure to the gas. The half-life of CO in normal room air is four to five hours. This means that, in four to five hours, half of the CO bound to hemoglobin will be replaced with oxygen. At normal atmospheric pressures, but breathing 100% oxygen, the half-life for the elimination of CO from the body is 50–70 minutes. In hyperbaric therapy at three atmospheres of pressure, the half-life is reduced to 20–25 minutes.

Although the symptoms of CO poisoning may subside in a few hours, some patients show memory problems, fatigue, confusion, and mood changes for two to four weeks after their exposure to the gas.

Prevention

Carbon monoxide poisoning is preventable. Particular care should be paid to situations where fuel is burned in a confined area. Portable and permanently installed carbon monoxide detectors that sound a warning similar to smoke detectors are available for less than $50. Specific actions that will prevent CO poisoning include:

- stopping smoking. Smokers have less tolerance to environmental CO
- having heating systems and appliances installed by a qualified contractor to assure that they are properly vented and meet local building codes
- inspecting and properly maintaining heating systems, chimneys, and appliances
- not using a gas oven or stove to heat the home
- not burning charcoal indoors
- making sure there is good ventilation if using a kerosene heater indoors
- not leaving cars or trucks running inside the garage
- keeping car windows rolled up when stuck in heavy traffic, especially if inside a tunnel

Carcinoembryonic antigen test

Definition

The carcinoembryonic antigen (CEA) test is a laboratory blood study. CEA is a substance that is normally found only during fetal development, but may reappear in adults who develop certain types of cancer. CEA is produced when there is rapid multiplication of epithelial cells such as those of the digestive track. CEA is also found in the blood of individuals who are chronic smokers.

Purpose

The CEA test is ordered for patients with known cancers. It is most commonly ordered when a patient has a cancer of the gastrointestinal system. These include cancer of the colon, rectum, stomach (gastric cancer), esophagus, liver, or pancreas. It is also used with cancers of the breast, lung, or prostate.

The CEA level in the blood is one of the factors that doctors consider when determining the prognosis, or most likely outcome of a cancer. In general, a higher CEA level predicts a more severe disease, one that is less likely to be curable. But it does not give clear-cut information. The results of a CEA test are considered along with other laboratory and/or imaging studies to follow the course of the disease.

Once treatment for the cancer has begun, CEA tests have a valuable role in monitoring the patient's progress. A decreasing CEA level means therapy is effective in fighting the cancer. A stable or increasing CEA level may mean the treatment is not working, and/or that the tumor is growing. It is important to understand that serial CEA measurements, several done over a period of time, are the most useful. A single test result is difficult to evaluate, but a number of tests, done weeks apart, shows trends in disease progression or regression.

Certain types of cancer treatments, such as hormone therapy for **breast cancer**, may cause the CEA level to go up. This elevation does not accurately reflect the state of the disease. It is sometimes referred to as a "flare response." Recognition that a rise in CEA may be temporary and due to therapy is significant. If this possibility is not taken into account, the patient may be unnecessarily discouraged. Further, treatment that is actually effective may be stopped or changed prematurely.

CEA tests are also used to help detect recurrence of a cancer after surgery and/or other treatment has been completed. A rising CEA level may be the first sign of cancer return, and may show up months before other studies or patient symptoms would raise concern. Unfortunately, this does not always mean the recurrent cancer can be cured. For example, only a small percentage of patients with colorectal cancers and rising CEA levels benefit from another surgical exploration. Those with recurrence in the same area as the original cancer, or with a single metastatic tumor in the liver or lung, have a chance that surgery will eliminate the disease. Patients with more widespread return of the cancer are generally not treatable with surgery. The CEA test will not separate the two groups.

Patients who are most likely to benefit from non–standard treatments, such as bone marrow transplants, may be determined on the basis of CEA values, combined with other test results. CEA levels may be one of the criteria for determining whether the patient will benefit from more expensive studies, such as CT scan or MRI.

Description

Determination of the CEA level is a laboratory blood test. Obtaining a specimen of blood for the study takes only a few minutes. CEA testing should be covered by most insurance plans.

The CEA test is not a screening test for cancer. It is not useful for detecting the presence of cancer since many cancers do not produce an increased CEA level. Some noncancerous diseases, such as hepatitis, inflammatory bowel disease, **pancreatitis**, and obstructive pulmonary disease, may cause an elevated CEA level.

Preparation

No preparation is required.

KEY TERMS

False negative—Results of testing indicates that cancer is not present when cancer is indeed present in the body.

False positive—Results of testing indicates that cancer is present when cancer is not present in the body.

Serial monitoring—Monitoring of results of several blood tests over time to detect a pattern of increasing, decreasing, or unchanging values in the blood.

Aftercare

No specific aftercare measures are required. Results will be sent to the healthcare provider who ordered the test originally. The health care provider will then discuss results with the patient.

Risks

There are no complications or side effects of this test. However, the results of a CEA study should be interpreted with caution. A single test result may not yield clinically useful information. Several studies over a period of months may be needed.

Another concern is the potential for false positive or false negative results. A false positive result means the test shows an abnormal value when cancer is not present. A false negative means the test reveals a normal value when cancer actually is present.

Results

The absolute numbers that are considered normal vary from one laboratory to another. Any results reported should come with information regarding the testing facility's normal range.

Abnormal results

A single abnormal CEA value may be significant, but must be regarded cautiously. In general, very high CEA levels indicate more serious cancer, with a poorer chance for cure. But some benign diseases and certain cancer treatments may produce an elevated CEA test. Cigarette **smoking** will also cause the CEA level to be abnormally high.

Carcinogens

Definition

Carcinogens are substances capable of causing cancer. The United States Environmental Protection Agency (EPA) classifies many substances on the basis of their potential for causing cancer. Classifications are based on results of studies on animals or experience with humans. Classification categories refer to epidemiological studies, which are studies to identify the factors controlling the presence or absence of a disease.

Description

Group A, or Human Carcinogens, are substances for which there is a relationship between the substance and cancer that has been conclusively demonstrated through epidemiological studies of humans. Group B, or Probable Human Carcinogens are composed of two types of carcinogens. There is sufficient evidence from animal studies and limited epidemiological studies that B1 carcinogens cause cancer. B2 carcinogens are classified on the basis of sufficient evidence from animal studies only; epidemiological data are inadequate or nonexistent. Group C or Possible Human Carcinogens are substances where there is limited evidence from animal studies and no human epidemiological data. Group D or Not Classifiable as to Human Carcinogenicity are substances for which information is inadequate or completely lacking, so no assessment of the substance's cancer–causing potential is possible. Group E or Evidence of Noncarcinogenicity for Humans are substances that have

WWW.BOOKBAZ.IR

tested negative in at least two adequate animal cancer tests in different species and in adequate epidemiological and animal studies.

As of 2014, the International Agency for Research on Cancer (IARC) has determined that the following list of agents and mixtures are carcinogenic to humans.

- Acetaldehyde associated with consumption of alcoholic beverages
- Acid mists, strong inorganic
- Aflatoxins (naturally occurring)
- 4–Aminobiphenyl
- Alcoholic beverages
- Aluminium production
- Areca nut
- Aristolochic acid
- Aristolochic acid–containing plants
- Arsenic and arsenic compounds
- Asbestos, all forms
- Auramine production
- Azathioprine
- Benzene (used in nail polish remover, varnishes, airplane dopes, lacquers, and as a solvent)
- Benzidine and benzidine dyes
- Benzopyrene
- Betel quid with and without tobacco
- Beryllium and beryllium compounds
- N,N–Bis (2–Chloreothyl)–2–Naphthylamine (Chlomophaozine)
- Bis(chloromethyl) ether and technical grade chloromethyl methyl ether
- Busulphan (Myleran)
- 1, 3–Butadiene
- Cadmium and cadmium compounds
- Chlorambucil
- Chlornaphazine)
- Chromium and certain chromium compounds
- Clonorchis sinensis, infection with
- Coal, indoor emissions and gasification
- Coal–tar distillation
- Coke production
- Cyclophosphamide
- Cyclosporin (ciclosporin)
- Diethystilbestrol (DES)
- Epstein–Barr virus
- Erionite
- Estrogen therapy, postmenopausal
- Estrogen–progesterone combined menopausal therapy
- Estrogen–progesterone combined oral contraceptives
- Ethanol in alcoholic beverages
- Ethylene oxide
- Etoposide
- Etoposide in combination with cisplatin and bleomycin
- Fission products, including strontium–90
- Formaldehyde
- Haematite underground mining
- Helicobacter pylori, infection with
- *Helicobacter pylori* (infection)
- Hepatitis B and C virus (chronic infection)
- HIV virus type 1
- Human papillomavirus (HPV) types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59
- Human T–cell lypmhotropic virus type 1
- Ionizing radiation of all types
- Iron and steel founding occupational exposure
- Isopropyl alcohol manufacture using strong acids
- Kaposi sarcoma herpes virus
- Leather dust
- Magenta production
- Melphalan
- Methoxsalen with ultraviolet A radiation
- Mineral oils which are untreated or mildly treated
- MOPP and other combined chemotherapy especially alkylating agents
- 2–Naphthylamine
- Neutron radiation
- Nickel compounds
- N–Nitrosonornicotine (NNN) and 4–1–1–butanone (NNK)
- *Opisthorchis viverrini* (infection)
- Painter, occupational exposure
- 3,4,5,3,4–Pentachlorobiphenyl (PCB–126)
- 2,3,4,7,8–Pentachlorodibenzofuran
- Phenacetin and phenacetin–containing analgesic mixtures
- Phosphorus–32
- Plutonium
- Radioiodines, such as I–131
- Radionuclides, alpha–and beta–particle emission when internally deposited
- Radium–224, 226, and 228
- Radon–222
- Rubber industry (certain occupations)

- Salted fish, Chinese style
- Schistosoma haematobium, infection with
- Semsustine–3–1–nitrosurea, Methyl–CCNU
- Shale oils
- Silica
- Solar radiation
- Soot
- Sulfur mustard
- Tamoxifen (There is also evidence that this agent protects against contralateral breast cancer.)
- 2,3,7,8–Tetrachlorodibenzo–para–dioxin
- Thiotepa
- Thorium–232
- Tobacco, smoking, smokeless, and second–hand smoke
- Ortho–Toluidine
- Treosulfan
- Ultraviolet radiation encompassing UVA, UVB, and UVC
- Ultraviolet–emitting tanning devices
- Vinyl chloride
- Wood dust
- X- and Gamma radiation

Cardiac catheterization

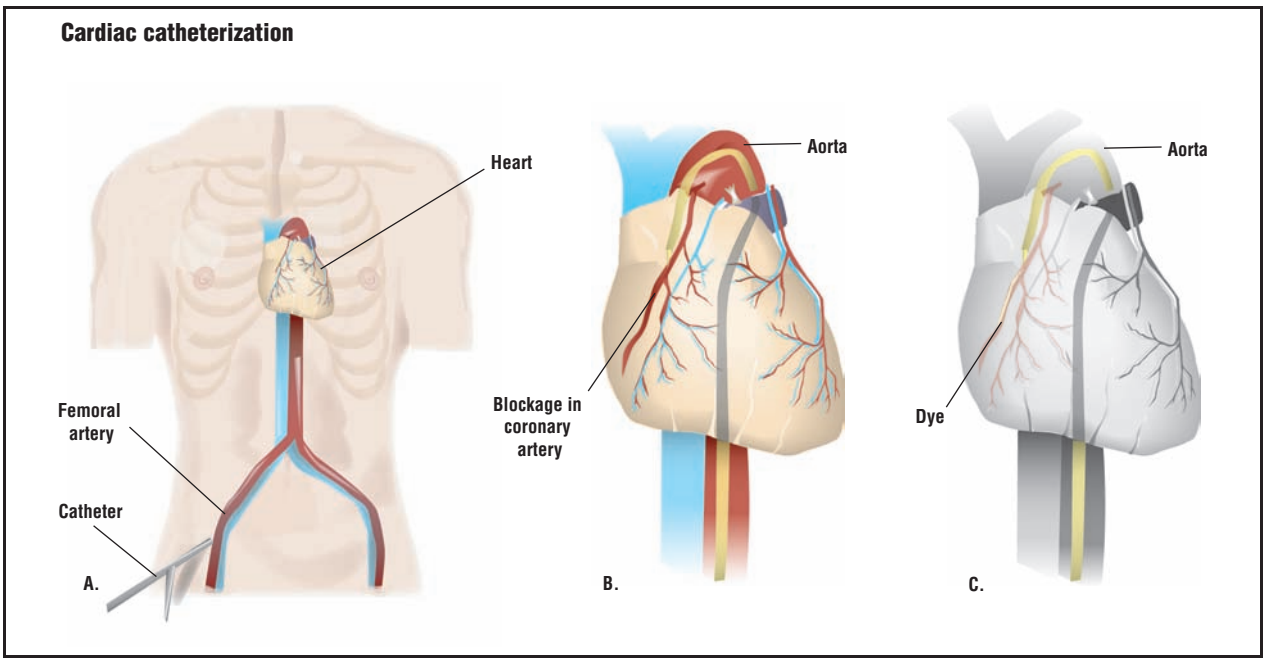
Definition

Cardiac catheterization, also called heart catheterization, is a diagnostic and sometimes therapeutic invasive procedure that allows a comprehensive examination of the heart, its four chambers, valves, and surrounding blood vessels. It also offers heart surgeons the opportunity to perform necessary repairs under direct visualization. Even while noninvasive testing is improving, cardiac catheterization is the standard for evaluating hemodynamics, including heart function and blood flow. Cardiac catheterization is performed by inserting one or more catheters (thin flexible tubes) into the heart through a peripheral blood vessel in the arm (antecubital artery or vein) or leg (femoral artery or vein) under x-ray guidance. It enables physicians to perform angiograms; record blood flow; calculate oxygen saturation, cardiac output, and vascular resistance; perform endomyocardial biopsy; and evaluate the heart's electrical activity.

Purpose

Cardiac catheterization is most commonly performed to examine the coronary arteries in which diseases that cause heart attacks, **angina**, sudden death, and **heart failure** most often originate. It is used primarily to diagnose **coronary artery disease** and also may reveal the presence of other conditions of the heart chambers or valves, including enlargement of the left ventricle, ventricular aneurysms (abnormal dilation of a blood vessel), narrowing of the aortic valve, insufficiency of the aortic or mitral valve, and septal defects that result in an abnormal flow of blood from one side of the heart to the other.

WWW.BOOKBAZ.IR



During cardiac catheterization, a catheter is fed into the femoral artery of the upper leg (A). The catheter is fed up to coronary arteries to an area of blockage (B). A dye is released, allowing visualization of the blockage (C). *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

Symptoms and diagnoses that may be associated with the above conditions and may lead to cardiac catheterization include:

- chest pain characterized by prolonged heavy pressure or a squeezing pain
- abnormal results from a treadmill stress test
- myocardial infarction (heart attack)
- congenital heart defects
- vascular disease such as coronary artery disease
- valvular disease

Cardiac catheterization with coronary **angiography** is recommended in patients with angina (especially unstable angina); suspected coronary artery disease; suspected silent ischemia with family history of **heart attack**, **congestive heart failure**, **congenital heart disease**, and pericardial disease (the pericardium is the layer of thin tissue covering the heart). Catheterization is also recommended for patients with suspected heart valve disease, including **aortic valve stenosis** (narrowing) or regurgitation, and **mitral valve stenosis** or regurgitation.

Patients with congenital cardiac defects are also evaluated with cardiac catheterization to visualize the abnormal direction of blood flow associated with these diseases. In addition, the procedure may be performed after acute myocardial infarction (heart attack), before major noncardiac surgery in patients at high risk for cardiac problems, before cardiac surgery in patients at risk for coronary artery disease, and before such interventional technologies and procedures as stent placement and percutaneous transluminal coronary **angioplasty** (PTCA) or the closure of small openings between the upper chambers of the heart (atria), called atrial septal defects. It may also be applied to confirm the results of other noninvasive testing.

Left- and right-side catheterization

Cardiac catheterization can be performed on either side of the heart to evaluate different functions. Testing the right side of the heart allows the physician to evaluate tricuspid and pulmonary valve function, in addition to measuring blood pressures and collecting blood samples from the right atrium, right ventricle (lower chamber), and pulmonary artery. Catheterization of the left side of the heart is performed to test the blood flow in the coronary arteries, as well as the level of function of the mitral and aortic valves and left ventricle.

Coronary angiography

Coronary angiography, also known as coronary arteriography, is an imaging technique that involves injecting a dye into the vascular system to outline the heart and coronary vessels. Angiography allows the

KEY TERMS

Aneurysm—An abnormal dilatation of a blood vessel, usually an artery such as the aorta, that may be caused by a congenital defect or weakness in the vessel's wall.

Angiography—A procedure that allows x-ray examination of the heart and coronary arteries following injection of a radiopaque substance (often referred to as a dye or contrast agent) to enhance the visualization.

Angioplasty—A procedure in which a balloon catheter is used to mechanically dilate the affected area of a diseased artery and enlarge the constricted or narrowed segment; it is an alternative to vascular surgery.

Aortic valve—The valve between the heart's left ventricle and ascending aorta that prevents regurgitation of blood back into the left ventricle.

Arrhythmia—A variation in the normal rhythm of the heartbeat.

Catheter—A flexible or pre-shaped curved tube, usually made of plastic, used to evacuate fluids from or inject fluids into the body.

Computed tomography (CT)—A diagnostic imaging procedure that uses x rays to produce cross-sectional images of the anatomy.

Coronary bypass surgery—A surgical procedure that places a shunt to allow blood to travel from the aorta to a branch of the coronary artery at a point below an obstruction.

Doppler ultrasonography—A diagnostic ultrasound procedure that uses reflected sound waves to evaluate blood flow through major arteries and veins.

Echocardiography—An ultrasound examination of the heart to evaluate structure and blood flow.

Fluoroscopy—A diagnostic imaging procedure that uses x rays and contrast agents to visualize anatomy and motion in real time.

Hematoma—An accumulation of clotted blood that may occur in the tissue around a catheter insertion site.

Ischemia—A localized deficiency in the blood supply, usually caused either by vasoconstriction or by obstacles to the arterial blood flow.

Magnetic resonance imaging (MRI)—A diagnostic imaging procedure that uses a magnetic field to produce anatomical images.

Mitral valve—The bicuspid valve that lies between the left atrium and left ventricle of the heart.

Percutaneous transluminal coronary angioplasty (PTCA)—A cardiac intervention in which an artery blocked by plaque is dilated, using a balloon catheter to flatten the plaque and open the vessel; it is also called balloon angioplasty.

Pericardial tamponade—The collection of blood in the sac surrounding the heart that causes compression.

Pseudoaneurysm—A dilation of a blood vessel that resembles an aneurysm.

Pulmonary valve—The heart valve that separates the right ventricle and the opening into the pulmonary artery.

Septum—The muscular wall that separates the two sides of the heart; an opening in the septum that allows blood to flow from one side to the other is called a septal defect.

Shunt—A passageway (or an artificially created passageway) that diverts blood flow from one main route to another.

Stent—A small tube-like device made of stainless steel or other material, used to hold open a blocked artery.

Tricuspid valve—The right atrioventricular valve of the heart; it has three flaps, whereas the mitral valve has only two.

visualization of any blockages, narrowing, or abnormalities in the coronary arteries. If these signs are visible, the cardiologist may assess the patient's readiness for coronary bypass surgery, or a less invasive approach such as dilation of a narrowed blood vessel by surgery or the use of a balloon (angioplasty). Because some interventions may be performed during cardiac catheterization, the procedure is considered therapeutic as well as diagnostic.

Demographics

Coronary artery disease is the first-ranked cause of death for both men and women in the United States. More than 1.5 million cardiac catheterizations are performed every year in the United States, primarily to diagnose or monitor **heart disease**. There is an expected growth to more than 3 million procedures by 2010.

WWW.BOOKBAZ.IR

Description

Cardiac anatomy

The heart consists of four chambers separated by valves. The right side of the heart, which consists of the right atrium (upper chamber, sometimes called the right auricle) and the right ventricle (lower chamber), pumps blood to the lungs. The left side of the heart, which consists of the left atrium and the left ventricle, simultaneously pumps blood to the rest of the body. The right and left coronary arteries, which are the first vessels to branch off from the aorta, supply blood to the heart. The left anterior descending coronary artery supplies the front of the heart; the left circumflex coronary artery wraps around and supplies the left side and the back of the heart; and the right coronary artery supplies the back of the heart. There is, however, a considerable amount of variation in the anatomy of the coronary arteries.

Catheterization procedure

The patient lies face up on a table during the catheterization procedure, and is connected to a cardiac monitor. The insertion site, which may be a blood vessel in the wrist, arm, groin, or neck, is numbed with a local anesthetic, and access to the vein or artery is obtained using a needle. A rigid plastic tube (sheath) that facilitates insertion of catheters and infusion of drugs, is placed in the puncture site. Under fluoroscopic guidance, a guide-wire (a thin wire that guides the catheter insertion) is threaded through a brachial or femoral artery into the heart. The catheter, a flexible or pre-shaped tube approximately 32–43 in. (80–110 cm) long, is then inserted over the wire and threaded into the arterial side of the heart. The patient may experience pressure as the catheter is threaded into the heart. The contrast agent, or dye, used to enhance imaging is then injected so that the physician can view the heart and surrounding vessels. The patient may experience a hot, flushed feeling or slight nausea following injection of the contrast medium. Depending on the type of catheterization (left or right heart) and the area being imaged, different catheters with various shapes and ends are used. Samples of blood and heart muscle may be taken during catheterization, or minor heart surgery or procedures such as angioplasty, percutaneous coronary intervention (PCI), balloon septostomy, or **catheter ablation** may be done to correct defects. Firm pressure is applied to the insertion site after the procedure.

The radiographic/fluoroscopic system has an x-ray subsystem and video system with viewing monitors that allow the physician to observe the procedure in real time using fluoroscopy as well as taking still x rays for documentation purposes. Most newer systems use a digital angiography system that allows images to be recorded, manipulated, and stored digitally on a computer.

The procedure usually lasts two or three hours. If further intervention is necessary, an angioplasty, stent implantation, or other procedure can be performed. At the end of the catheterization, the catheter and sheath are removed, and the puncture site is closed using a sealing device or manual compression to stop the bleeding. One commonly used sealing device is called Perclose, which allows the doctor to sew up the hole in the groin. Other devices use collagen seals to close the hole in the femoral artery.

Diagnosis

Before undergoing cardiac catheterization, the patient may have had other noninvasive diagnostic tests, including an electrocardiogram (ECG), **echocardiography**, computed tomography (CT), **magnetic resonance imaging** (MRI), laboratory studies (e.g., blood work), and/or nuclear medicine cardiac imaging. The results of these noninvasive tests may have indicated a need for cardiac catheterization to confirm a suspected cardiac condition, further define the severity of a previously diagnosed condition, or establish the need for an interventional procedure (e.g., cardiac surgery).

Preparation

Patients are asked to give the physician or nurse a complete list of their regular medications, including **aspirin** and **nonsteroidal anti-inflammatory drugs** (NSAIDs), because they can affect blood coagulation. Patients with diabetes who are taking either metformin or insulin to control glucose metabolism should inform the physician, as dosage of these drugs may need to be changed before the procedure. Patients should also report any **allergies** to shellfish containing iodine, iodine itself, or the dyes commonly used as contrast agents before undergoing cardiac catheterization.

Because cardiac catheterization is considered a surgical procedure, the patient will be instructed to fast for at least six hours prior to the procedure. A mild sedative may be administered about an hour before the procedure to help the patient relax. If the catheter is to be inserted through the groin, the area around the patient's groin will be shaved and cleansed with an antiseptic solution.

Aftercare

While cardiac catheterization may be performed on an outpatient basis, the patient requires close monitoring following the procedure; the patient may have

to remain in the hospital for up to 24 hours. The patient will be instructed to rest in bed for at least eight hours immediately after the procedure. If the catheter was inserted into a vein or artery in the leg or groin area, the leg will be kept extended for four to six hours. If a vein or artery in the arm was used to insert the catheter, the arm will need to remain extended for a minimum of three hours.

Most doctors advise patients to avoid heavy lifting or vigorous **exercise** for several days after cardiac catheterization. Those whose occupation involves a high level of physical activity should ask the doctor when they could safely return to work. In most cases, a hard ridge will form over the incision site and will diminish as the site heals. A bluish discoloration under the skin often occurs at the point of insertion but usually fades within two weeks. The incision site may bleed during the first 24 hours following surgery. The patient may apply pressure to the site with a clean tissue or cloth for 10–15 minutes to stop the bleeding.

The patient should be instructed to call the doctor at once if tenderness, **fever**, shaking, or chills develop, which may indicate an infection. Other symptoms requiring medical attention include severe **pain** or discoloration in the leg, which may indicate that a blood vessel was damaged. These developments should be reported as soon as noticed.

Risks

Cardiac catheterization is categorized as an invasive procedure that involves the heart, its valves, and coronary arteries, in addition to a large artery in the arm or leg. Cardiac catheterization is contraindicated (not advised) for patients with the following conditions:

- severe anemia or bleeding disorder, or anticoagulation treatment with Coumadin (sodium warfarin), which may adversely affect bleeding and clotting during the catheterization procedure
- renal insufficiency or poor kidney functioning (especially in diabetic patients), which may worsen following angiography
- severe uncontrolled hypertension
- ventricular arrhythmias
- acute stroke
- gastrointestinal bleeding
- severe peripheral vascular disease that limits access to the arteries
- untreated active infections
- endocarditis (an inflammatory infection of the heart's lining that often affects the valves)
- electrolyte imbalances
- coexisting illnesses that may affect recovery or survival

Radiation hazards

Cardiac catheterization involves radiation exposure for staff members as well as the patient. The patient's dose of radiation is minimized by using lead shielding in the form of blankets or pads over certain body parts and by choosing the appropriate dose during fluoroscopy. To monitor staff members' exposure to radiation, they wear radiation badges that detect exposure and lead aprons that shield the body. The radiographic/fluoroscopic system may be equipped with movable lead shields that do not interfere with access to the patient and are placed between staff members and the source of radiation during the procedure.

Morbidity and mortality rates

As with all invasive procedures, cardiac catheterization involves some risks, but overall, serious complications are rare. The most serious complications include **stroke** and myocardial infarction. Other complications include cardiac **arrhythmias**, pericardial tamponade, vessel injury, and renal failure. One study demonstrated a total risk of major complications under 2% for all patients. The risk of death from cardiac catheterization has been demonstrated at 0.11%. The most common complications resulting from cardiac catheterization are vascular related, including external bleeding at the arterial puncture site, hematomas, and pseudoaneurysms.

The patient may be given anticoagulant medications to lower the risk of developing an arterial blood clot (thrombosis) or of **blood clots** forming and traveling through the body (embolization).

The risk of complications from cardiac catheterization is higher in patients over the age of 60, those who have severe heart failure, or those with advanced valvular disease.

Allergic reactions related to the contrast agent (dye) and anesthetics may occur in some patients during cardiac catheterization. Allergic reactions may range from minor **hives** and swelling to severe **shock**. Patients with allergies to seafood or penicillin are at a higher risk of allergic reaction—giving **antihistamines** prior to the procedure may reduce the occurrence of allergic reactions to contrast agents.

Results

Normal findings from a cardiac catheterization will indicate no abnormalities in the size or configuration of the heart chamber, the motion or thickness of its walls, the direction of blood flow, or motion of the

WWW.BOOKBAZ.IR

valves. Smooth and regular outlines indicate normal structure of the coronary arteries.

The measurement of intracardiac pressures, or the pressure in the heart's chambers and vessels, is an essential part of the catheterization procedure. Pressure readings that are higher than normal are significant for a patient's overall diagnosis. Pressure readings that are lower, other than those resulting from shock, are usually not significant.

The ejection fraction is also determined by performing a cardiac catheterization. The ejection fraction is a comparison of the quantity of blood ejected from the heart's left ventricle during its contraction phase with the quantity of blood remaining at the end of the left ventricle's relaxation phase. The cardiologist will look for a normal ejection fraction reading of 60–70%.

Abnormal results are obtained by viewing the still and live motion x rays during cardiac catheterization for evidence of coronary artery disease, poor heart function, disease of the heart valves, and septal defects.

The most prominent sign of coronary artery disease is narrowing or blockage (stenosis) in the coronary arteries, with narrowing greater than 50% considered significant. A clear indication for intervention by angioplasty or surgery is a finding of significant narrowing of the left main coronary artery and/or blockage or severe narrowing in the high left anterior descending coronary artery.

A finding of impaired wall motion is an additional indicator of coronary artery disease, an aneurysm, an enlarged heart, or a congenital heart problem. Using an ejection fraction test that measures wall motion, cardiologists regard an ejection fraction reading under 35% as increasing the risk of complications while also decreasing the possibility of a successful long- or short-term outcome from surgery.

Detecting the difference in pressure above and below the heart valve can verify the presence of valvular disease. The greater the narrowing, the higher the difference in pressure.

To confirm the presence of septal defects, measurements are taken of the oxygen content on both the left and right sides of the heart. The right heart pumps unoxygenated blood to the lungs, and the left heart pumps blood containing oxygen from the lungs to the rest of the body. Elevated oxygen levels on the right side indicate the presence of a left-to-right atrial or **ventricular shunt**. Low oxygen levels on the left side indicate the presence of a right-to-left shunt.

Alternatives

Other methods of visualization such as noninvasive **ultrasound** imaging are applied to limit radiation exposure when evaluating the coronary arteries. Imaging of general cardiac architecture and valvular function can be visualized by noninvasive cardiac ultrasound. Cardiac ultrasound and Doppler ultrasound can be used together to observe valvular insufficiency and stenosis as well as to identify blood clots in major veins and arteries throughout the body. Areas of poor myocardial function can also be evaluated by ultrasound.

Nuclear medicine scans of the heart can show the perfusion of blood to a region of the myocardium. If blockages of the coronary artery exist, blood flow will be reduced. By adding a radioactive marker to the blood, images are generated to show areas of poor perfusion. Combined with exercise, these tests can accurately demonstrate cardiovascular disease. However, the imaging process can take several hours, and the patient is still internally exposed to high levels of radiation.

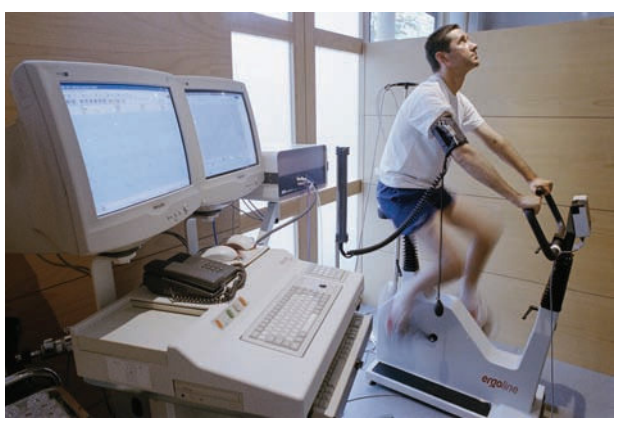
Cardiac rehabilitation

Definition

Cardiac **rehabilitation** is a comprehensive **exercise**, education, and behavioral modification program designed to improve the physical and emotional condition of patients with **heart disease**.

Purpose

Heart attack survivors, bypass and **angioplasty** patients, and individuals with **angina**, **congestive heart failure**, and heart transplants are all candidates for a cardiac rehabilitation program. Cardiac rehabilitation is prescribed to control symptoms, improve exercise tolerance, and improve the overall quality of life in these patients.



Man undergoing cardiac rehabilitation after receiving a heart transplant. *(RAJAU/PHANIE/Photo Researchers, Inc.)*

Precautions

A cardiac rehabilitation program should be implemented and closely monitored by a trained team of healthcare professionals.

Description

Cardiac rehabilitation is overseen by a specialized team of doctors, nurses, and other healthcare professionals. Members of the cardiac rehabilitation team may include a dietician or nutritionist, physical therapist, exercise physiologist, psychologist, vocational counselor, occupational therapist, and social worker. The program frequently begins in a hospital setting and continues on an outpatient basis after the patient is discharged over a period of six to 12 months.

Components of a cardiac rehabilitation program vary by individual clinical need, and each program will be carefully constructed for the patient by his or her rehabilitation team.

- Exercise. Exercise programs typically start out slowly, with simple range-of-motion arm and leg exercises. Walking and stair climbing soon follow. Blood pressure is carefully monitored before and after exercise sessions, and patients are taught how to measure their heart rate and evaluate any possible cardiac symptoms during each session. Patients with advanced coronary disease may require continuous ECG monitoring throughout their exercise sessions. Once discharged from the hospital, the patient works with his cardiac team to create an individual exercise plan.
- Diet. Cardiac patients will work with a nutritionist or dietician to develop a low-fat, low-cholesterol diet plan. Patients with high blood pressure may be put on a salt-restricted diet and instructed to limit alcohol intake. Weight loss may also be a goal with obese cardiac patients.
- Counseling. A psychologist or social worker can help cardiac patients with issues that may be contributing to their heart condition, such as stress and anxiety. Relaxation techniques may be taught to patients to help them deal with these feelings. Cardiac patients frequently experience a period of depression, and group or individual counseling can be beneficial in overcoming these feelings. Vocational counselors can assist cardiac patients in returning to the workforce.
- Education. The patient and family should be fully educated on the physical limitations of the patient, his recommended diet and exercise plan, his

WWW.BOOKBAZ.IR

KEY TERMS

Angina—Chest pain.

Bypass surgery—A surgical procedure that grafts blood vessels onto arteries to reroute the blood flow around blockages in the arteries (arteriosclerosis).

emotional status, and the lifestyle changes required to improve the patient's overall health.

- Smoking cessation. Cardiac patients who smoke are twice as likely to have a heart attack in the following five years than non-smoking patients. These patients are strongly encouraged to enroll in a smoking cessation program, which typically includes patient education and behavioral counseling. Nicotine replacement therapy, which uses nicotine patches, nose spray, or gum to wean patients off of cigarettes, may also be part of the program. Antidepressants and anti-anxiety medication may be helpful in some cases.

Aftercare

Long-term maintenance is a critical feature of cardiac rehabilitation. Patients require support from their healthcare team, family, and friends to continue the lifestyle changes they implemented during the rehabilitation period.

Risks

The risks of another heart attack during cardiac rehabilitation are slight, and greatly reduced by careful, continuous monitoring of the physical status of the patient.

The outcome of the cardiac rehabilitation program depends on a number of variables, including patient follow-through, type and degree of heart disease, and the availability of an adequate support network for the patient. Patients who successfully complete the program will ideally reach an age-appropriate level of physical activity and be able to return to the workforce and/or other daily activities.

Cardiac tamponade

Definition

Cardiac tamponade occurs when the heart is squeezed by fluid that collects inside the sac that surrounds it.

Description

The heart is surrounded by a sac called the pericardium. When this sac becomes filled with fluid, the liquid presses on the heart, preventing the lower chambers of the heart from properly filling with blood.

Because the lower chambers (the ventricles) cannot fill with the correct amount of blood, less than normal amounts of blood reach the lungs and the rest of the body. This condition is very serious and can be fatal if not treated.

Causes and symptoms

Fluid can collect inside the pericardium and compress the heart when the kidneys do not properly remove waste from the blood, when the pericardium swells from unknown causes, from infection, or when the pericardium is damaged by cancer. Blunt or penetrating injury from **trauma** to the chest or heart can also result in cardiac tamponade when large amounts of blood fill the pericardium. Tamponade can also occur during heart surgery.

When the heart is compressed by the surrounding fluid, three conditions occur: a reduced amount of blood is pumped to the body by the heart, the lower chambers of the ventricles are filled with a less than normal amount of blood, and higher than normal blood pressures occur inside the heart, caused by the pressure of the fluid pushing in on the heart from the outside.

When tamponade occurs because of trauma, the sound of the heart beats can become faint, and the blood pressure in the arteries decreases, while the blood pressure in the veins increases.

In cases of tamponade caused by more slowly developing diseases, **shortness of breath**, a feeling of tightness in the chest, increased blood pressure in the large veins in the neck (the jugular veins), weight gain, and fluid retention by the body can occur.

Diagnosis

When cardiac tamponade is suspected, accurate diagnosis can be life-saving. The most accurate way to

KEY TERMS

Pericardiocentesis—A procedure used to drain fluid out of the sac surrounding the heart. This is done by inserting a needle through the chest and into the sac.

identify this condition is by using a test called an echocardiogram. This test uses sound waves to create an image of the heart and its surrounding sac, making it easy to visualize any fluid that has collected inside the sac.

Treatment

If the abnormal fluid buildup in the pericardial sac is caused by cancer or **kidney disease**, drugs used to treat these conditions can help lessen the amount of fluid collecting inside the sac. Drugs that help maintain normal blood pressure throughout the body can also help this condition; however, these drugs are only a temporary treatment. The fluid within the pericardium must be drained out to reduce the pressure on the heart and restore proper heart pumping.

The fluid inside the pericardium is drained by inserting a needle through the chest and into the sac itself. This allows the fluid to flow out of the sac, relieving the abnormal pressure on the heart. This procedure is called **pericardiocentesis**. In severe cases, a tube (catheter) can be inserted into the sac or a section of the sac can be surgically cut away to allow for more drainage.

Prognosis

This condition is life-threatening. However, drug treatments can be helpful, and surgical treatments can successfully drain the trapped fluid, though it may reaccumulate. Some risk of death exists with surgical drainage of the accumulated fluid.

Cardiomyopathy

Definition

Cardiomyopathy is a chronic disease of the heart muscle (myocardium), in which the muscle is abnormally enlarged, thickened, and/or stiffened. The weakened heart muscle loses the ability to pump blood effectively, resulting in irregular heartbeats (**arrhythmias**) and possibly even **heart failure**.

Description

Cardiomyopathy, a disease of the heart muscle, primarily affects the left ventricle, which is the main pumping chamber of the heart. The disease is often associated with inadequate heart pumping and other heart function abnormalities. Cardiomyopathy is not common (affecting about 50,000 persons in the United States) but it can be severely disabling or fatal. Severe cases may result in heart failure and will require a heart transplant for patient survival. Cardiomyopathy is a heart condition that not only affects middle-aged and elderly persons, but can also affect infants, children, and adolescents.

There are four major types of cardiomyopathy:

- Dilated (congestive cardiomyopathy). This is the most common form of the disease. The heart cavity is enlarged and stretched (cardiac dilation), which results in weak and slow pumping of the blood, which in turn can result in the formation of blood clots. Abnormal heart rhythms (arrhythmias) and disturbances in the electrical conduction processes in the heart may also occur. Most patients with this type of cardiomyopathy develop congestive heart failure. There is also a genetically-linked cardiac disease, Barth syndrome, that can cause dilated cardiomyopathy. This syndrome affects male children, and is usually diagnosed at birth or within the first few months of life. Pregnant women during the last trimester of pregnancy or after childbirth may develop a type of dilated cardiomyopathy referred to as peripartum cardiomyopathy.
- Hypertrophic cardiomyopathy. With this type of cardiomyopathy, the muscle mass of the left ventricle enlarges, or hypertrophies. In hypertrophic obstructive cardiomyopathy (HOCM), the septum (wall) between the two heart ventricles (the pumping chambers) becomes enlarged and obstructs blood flow from the left ventricle. The thickened wall can also distort one leaflet of the mitral valve, which results in leakage. HOCM is most common in young adults. HOCM is often hereditary, caused by genetic

WWW.BOOKBAZ.IR

mutations in the affected person's DNA. The disease is either inherited through one parent who is a carrier or through both parents who each contribute a defective gene. HOCM is also referred to as asymmetrical septal hypertrophy (ASH) or idiopathic hypertrophic subaortic stenosis (IHSS). In another form of hypertrophic cardiomyopathy, non-obstructive cardiomyopathy, the enlarged heart muscle does not obstruct the blood flow through the heart.

- Restrictive cardiomyopathy. This is a less common type of cardiomyopathy, in which the heart muscle of the ventricles becomes rigid. Restrictive cardiomyopathy affects the diastolic function of the heart, that is, it affects the period when the heart is relaxing between contractions. Since the heart cannot relax adequately between contractions, it is harder for the ventricles to fill with blood between heartbeats. This type of cardiomyopathy is usually the result of another disease.
- Arrhythmogenic right ventricular cardiomyopathy (ARVC). ARVC is very rare and is believed to be an inherited condition. With ARVC, heart muscle cells become disorganized and damaged and are replaced by fatty tissues. The damage appears to be a result of the body's inability to remove damaged cells. The damaged cells are replaced with fat, leading to abnormal electrical activity (arrhythmias) and abnormal heart contractions. ARVC is the most common cause of sudden death in athletes.

Causes and symptoms

Cardiomyopathy may be caused by many different factors, including viral infections (e.g., **myocarditis**), heart attacks, **alcoholism**, long-term, severe high blood pressure, genetic neuromuscular diseases (e.g., muscular dystrophies and ataxias), genetic metabolic disorders, complications from **AIDS**, and other reasons that have not yet been identified (idiopathic cardiomyopathy). Cardiomyopathy caused by heart attacks (referred to as ischemic cardiomyopathy) results from scarring in the heart muscle. Larger **scars** or more numerous heart attacks increases the risk that ischemic cardiomyopathy will develop. Alcoholic cardiomyopathy usually develops about 10 years after sustained, heavy alcohol consumption. Other toxins that may cause cardiomyopathy include drugs and radiation exposure.

The major symptoms of cardiomyopathy include:

- shortness of breath
- temporary and brief loss of consciousness, especially after engaging in activity
- lightheadness, especially after engaging in activity
- decreased ability to tolerate physical exertion
- fatigue
- dizziness
- palpitations, that is, the sensation of feeling the heart beat
- chest pain (angina), whereby there is a feeling of sharp and unrelenting pressure in the middle of the chest (especially experienced by persons whose cardiomyopathy is a result of a previous heart attack)
- high blood pressure

Other symptoms that may be associated with cardiomyopathy include:

- abdominal swelling or enlargement
- swelling of legs or ankles
- low amount of urine during the daytime, but a need to urinate at night
- decreased alertness and difficulty concentrating
- cough
- loss of appetite

Diagnosis

A complete **physical examination** and **health history** review by a health care provider is recommended if a person is suspected to have cardiomyopathy. The examination may reveal the presence of an irregular heartbeat, heart murmur, or other abnormal heart and breath sounds.

Various invasive and non-invasive tests are performed as diagnostic tools for cardiomyopathy. An echocardiogram is the most informative noninvasive test for diagnosing the type of cardiomyopathy and the degree of dysfunction in the heart muscle. High frequency sound waves produce moving images of the beating heart on a video screen, which allows the measurement of muscle thickness, size, pumping ability, degree of obstruction, chamber size, and heart valve movement.

The use of non-invasive radiation-based imaging procedures, such as chest radiography, computed tomography (CT), or **magnetic resonance imaging** (MRI) procedures show the size, shape, and structure of the heart. If dilated cardiomyopathy is suspected, one of these techniques is performed first to see if the heart is enlarged and whether there is any fluid accumulation in the lungs.

An electrocardiogram (EKG) is a non-invasive procedure where electrodes are placed on the person's limbs and chest wall to provide a graphic record of the electrical activity of the heart. This test can show the amount of heart enlargement and reveal abnormal

heart rhythms. Children with a normal echocardiogram may have an abnormal EKG, indicating that they may be a carrier of the cardiomyopathy gene and may develop the disease later in life. A person may also wear a Holter monitor, which is an external device that continuously records heart rhythms. The monitor can identify irregular heart rhythms associated with dilated, hypertrophic, or **restrictive cardiomyopathy**.

Genetic studies may help in understanding the cause of cardiomyopathy, since the disease may be a symptom of another genetic disorder. If a child under the age of 4 has cardiomyopathy, metabolic screening should be performed, for certain metabolic disorders with cardiomyopathy as a symptom can be controlled with a change in diet, drug therapy, or by a bone marrow transplant, which may reduce or reverse the progression of the cardiomyopathy. Since cardiomyopathy can be inherited and present initially without signs or symptoms, relatives of a patient with the disease should be screened periodically for evidences of the disease.

Invasive procedures, which involve the use of **anesthesia**, are used to determine the severity of the disease. In the radionuclide ventriculogram procedure, a low-dose radioactive material is injected into a vein and flows to the heart. The heart is photographed with a special camera to assess the contraction and filling of the ventricles at rest and with activity. **Cardiac catheterization** involves insertion of thin, flexible plastic tubes (catheters) into the heart from a blood vessel in the groin area. A dye is then injected that can indicate blood pressures, blood flow within the heart, and blockages in the arteries. Although rarely used, a heart muscle biopsy, where the doctor removes a few, tiny pieces of the heart for laboratory studies, can aid in diagnosing possible infections in the heart or metabolic abnormalities. An electrophysiology study is similar to heart catheterization. Catheters with fine wires are inserted through veins in the groin area into the heart. Electrical stimuli applied through the wires can indicate abnormal conduction pathways, arrhythmias, effectiveness of drugs, and the need for an implanted defibrillator.

Treatment

Although there is a long list of possible causes for cardiomyopathy, few are directly treatable or curable. Therefore, most therapy is directed toward treating the effects of the disease on the heart. If cardiomyopathy is diagnosed at an advanced stage, a critically ill patient will require immediate life-saving measures such as placement of a breathing tube and administration of medicines to improve heart function and blood pressure. Once the patient is stabilized, long-term therapy needs, such as oral medication, **pacemakers**, surgery, or **heart transplantation**, will be identified.

Initial treatments for cardiomyopathy for patients diagnosed in the earlier stages of cardiomyopathy include drug therapy to relieve heart failure, to decrease oxygen requirements and workload of the heart (by relaxing the arteries in the body), and to regulate abnormal heartbeats. Drugs that help the heart contract include **digoxin** for at-home use and dopamine, dobutamine, and milrinone for in-hospital use. **Diuretics** help relieve fluid overloads in heart failure. **Vasodilators**, ACE-inhibitors, and **beta blockers** dilate blood vessels in the body and lower blood pressure, thus reducing the workload for the heart. For patients at risk of developing **blood clots**, anticoagulation medication or blood thinners such as heparin or coumadin are prescribed along with diuretics such as Lasix and aldactone to relieve venous congestion. These drugs may result in side effects, so the patient must be carefully monitored to prevent complications.

When drugs are not effective or when arrhythmias require regulation, a pacemaker or a defibrillator may be implanted surgically into the patient. The procedures for implanting both devices involves placing a small mechanical device under the skin of the chest or abdomen with wire leads threaded through veins to the heart. A pacemaker is used to monitor and stabilize slow heartbeats, while a defibrillator ("an emergency room in the heart") detects and treats fast and potentially lethal heart rhythms. Since sudden death may occur in patients with cardiomyopathy, defibrillators are often recommended for persons who show evidence of arrhythmias.

For heart failure symptoms associated with restricted blood flow from the ventricles, septal **myomectomy**, which is considered major heart surgery, is sometimes recommended. This procedure involves surgical removal of the part of the thickened septal muscle that blocks the blood flow. In some cases, the mitral valve is replaced with an artificial valve. However, the procedure does not prevent sudden death due to hear arrhythmias nor does it stop the disease from progressing.

Since cardiomyopathy often becomes progressively worse, the heart can reach a state where it no longer responds to medication or to surgery. The treatment of "last resort" is a heart transplant, when the patient exhibits severe heart failure symptoms. A transplant

WWW.BOOKBAZ.IR

KEY TERMS

Arrhythmia—An abnormal rhythm or irregularity of the heartbeat. The heartbeat may either be too fast (tachycardia) or too slow (bradicardia). Arrhythmias may cause symptoms such as palpitation or lightheadedness, but many have more serious consequences, including sudden death.

Congestive heart failure—Potentially lethal condition in which congestion develops in the lungs that is produced by a heart attack, poorly controlled or uncontrolled hypertension, or disease processes that weaken the heart.

Hypertrophy—Literally means an increase in the muscle mass (or weight) of the heart.

Mitral valve leaflets—The mitral valve is made up of two valve leaflets (the anteromedial leaflet and the posterolateral leaflet) and a ring around the valve, known as the mitral valve annulus. The orientation of the two leaflets resembles a bishop's miter, which is where the valve receives its name.

Myocardium—The muscular wall of the heart located between the inner endocardial layer and the outer epicardial layer.

Noninvasive—Refers to tests that generally do not invade the integrity of the body, such as echocardiography or electrocardiography. (Cardiac catheterization, on the other hand, in which catheters are introduced through blood vessels into the heart, is an example of an invasive test).

Septum (ventricular septum)—That portion of the heart wall that divides the right and left ventricles.

Ventricles—The two main (lower) pumping chambers of the heart; the right and left ventricles pump blood to the lungs and aorta, respectively.

can cure the symptoms of heart failure, but the surgery carries significant risks, such as infection, organ rejection, and side effects of required medications.

There are surgical procedures that can be implemented to sustain life until a transplant donor becomes available. Left **Ventricular Assist Device** (LVAD) provides mechanical circulatory support, while Dynamic Cardiomyoplasty is a procedure whereby a skeletal-muscular flap, created from a patient's chest muscle, is first taught to contract and then is wrapped around the heart to aid in contraction.

Alternatives

Alternative treatments are directed toward control of the effects of **heart disease**. **Exercise**, diet, **nutrition**, herbal therapies, **stress reduction**, and other life style changes (e.g., cessation of **smoking**) can all be used to complement conventional treatments. Certain herbs such as fox glove (*Digitalis purpurea*) and lily of the valley (*Convallaria majalis*) contain cardiac glycosides that make them particularly potent and may cause dangerous side effects. Their use should be supervised only be a qualified medical herbalist, with the concurrence of the primary conventional health care provider. Even the use of less potent herbs that improve cardiac function, such as hawthorn (*Crataegus laevigata*), should be approved by the conventional health care provider and administered under the supervision of a medical herbalist.

Prognosis

Long-term prognosis can be unpredictable, as there can be a wide range of severities and outcomes associated with the disease. There is no cure, but some symptoms and complications can be managed and controlled with medication and implantable devices or with a heart transplant.

Prevention

Prevention of cardiomyopathy is focused on controlling risk factors for heart disease, which includes maintaining a healthy weight, exercising regularly, eating a well-balanced nutritious diet, and avoiding or minimizing smoking.

Judith Sims

Cardiopulmonary resuscitation

Definition

Cardiopulmonary resuscitation, commonly called CPR, is a lifesaving procedure performed when a person has stopped breathing or a person's heart has stopped beating.

Description

In 2013, about 359,000 Americans experienced cardiac arrest in settings outside a hospital. Some of these people were saved by the immediate application of CPR.

There are three physical symptoms that indicate a potential need for CPR to be performed immediately and for emergency medical support to be called: unconsciousness, absence of breathing, and no pulse detected (absence of heartbeat).

Unconsciousness

Unconsciousness is the loss of all awareness and failure to respond to questions, touch, or gentle shaking. When unconscious, a person cannot **cough** or clear the throat, which may allow the windpipe to become blocked, causing suffocation and death. People with a major illness or injury or who have had recent surgery are at risk for losing consciousness. Alcohol or **drug overdose** also can cause unconsciousness.

Individuals who are unconscious and not breathing need immediate CPR. Individuals who are unconscious and breathing (e.g., a traumatic **head injury**) need emergency medical care and should be watched to assure that their breathing continues. If individuals are conscious, they may be **choking** and need other medical help but do not need CPR. **Fainting** is a brief period of unconsciousness, which may occur from **dehydration** (lack of body fluids), low blood pressure, low blood sugar, excessive bleeding, or emotional distress. This is a temporary condition. Again, individuals may need medical help but do not normally need CPR because people who faint normally continue to breathe without assistance.

Failure to breathe

Apnea is the lack of spontaneous breathing. Individuals may become limp and lifeless, have a seizure, or turn bluish (a sign of inadequate oxygen). Prolonged apnea is called respiratory arrest. In children, this can quickly lead to cardiac arrest, meaning the heart stops beating. In adults, cardiac arrest usually happens first, followed by respiratory arrest. In adults, common causes of apnea and respiratory arrest include choking, drug overdose, near **drowning**, head injury, and cardiac arrest. In children, the causes may be different, such as **prematurity**, swelling of the airways (e.g., an **asthma** attack, an allergic reaction), choking on a foreign object, seizures, regurgitating food or near-drowning.

No pulse detected

If the rescuer is unable to detect a pulse or has difficulty feeling a pulse, it may be due to cardiac arrest (i.e., the heart has stopped beating). Not all rescuers are adept at finding a pulse in either the wrist or the carotid artery of the neck. Rescuers who are uncertain about whether there is a pulse should err on the side of caution and begin CPR.

Medical help and possibly CPR are needed immediately if any of these three symptoms are found. Time is critical. A local emergency number should be called immediately. If more than one person is available to help, one person can call the local emergency medical service (911 in the United States), while the other person begins CPR. If needed, the emergency dispatcher (the person who picks up emergency calls) can give step-by-step CPR instructions over the telephone.

Call 911 and immediately start CPR with chest compressions only. Push hard on the center of the chest 30 times (E) at a rate of 100 compressions/minute. If you're trained in CPR, continue by opening the airway with a head tilt (B). Pinch the victim's nose shut, inha *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Performing CPR

The American Heart Association recommends that doing something in the event there appears to be a need for CPR is always better than doing nothing, even if the rescuer is untrained. Different steps apply for people trained and untrained in CPR, but it is always better to err on the side of trying to provide CPR assistance than standing by and doing nothing. The explanation below is intended as a descriptive guideline only, not as a substitute for CPR training.

The American Heart Association has recommended that the three traditional steps for performing CPR be reordered for lay people who have had little or no training in CPR. This change applies to performing CPR on adults, children, and infants, but not on newborns. Formerly the steps were (in order): clear the airways, check for breathing, and begin chest compressions. This was known as the A-B-C method of CPR.

The recommended order was changed to C-A-B. Chest compressions should begin *first*, followed by clearing the airways and checking for breathing if the rescuer is adequately trained. There are two reasons for this change. First, most people have residual oxygen in their lungs from their last breath. It is most important that the blood be kept circulating continuously through chest compressions so that this oxygen reaches the brain without delay. Second, many lay people are reluctant to do mouth-to-mouth breathing on a stranger. After reviewing multiple studies that examined the outcome of CPR done by lay people, the American Heart Association determined that chest compressions alone, known as hands-only CPR, are almost as effective as chest compressions with breathing and that breathing need not be done by people untrained in CPR. The American Heart Association hopes that this change will encourage more bystanders to come to the aid of a cardiac arrest victim and potentially save more lives.

The steps to be followed in CPR by a layperson are as follows:

- If victims appear to be unconscious, they should be shaken or tapped gently to check for any sign of consciousness. If there is no response, the rescuer should call emergency medical services immediately or (preferably) send someone else to call for help. If the rescuer is alone, the person should call for emergency services before beginning CPR.
- Victims should be placed on their back on a level surface such as the ground or the floor unless there is some sign of neck or back injuries, in which case the individual should not be moved. It is better to err on the side of caution and not move the individual if there is any question about whether moving will cause additional damage.
- The rescuer then places the heel of one hand in the middle of the chest, putting the other hand on top of the first, interlacing the fingers, and pressing down so that the chest is compressed by at least two inches. Hard and fast compressions are essential if CPR is to be effective. The rescuer should not worry about damaging the breastbone or ribs. (These will heal; death is permanent.) When performing compressions, the rescuer should keep the elbows straight, center the shoulders over the victim, develop an up-and-down rhythm, and keep the hands firmly on the victim's chest. Compressions should be done on the center of the chest midway between the nipples. Compressions should be hard and fast at a rate of at least 100 times per minute. That is about the same rhythm as the beat of the Bee Gee's song "Stayin' Alive." Compressions should continue at this rate until the victim begins to breathe spontaneously or until trained medical help arrives.

A rescuer who is trained in CPR may first perform 30 chest compressions, then jut the victim's jaw forward, tilt the head back, and open the mouth. Using the finger, the rescuer should clear any debris from inside the mouth. The rscuer then should put an ear to the victim's open mouth, look for chest movement, listen for air flowing through the mouth or nose, and feel for air on the rescuer's cheek. If there is no breathing, the rescuer pinches the individual's nose shut, makes a seal over the individual's mouth with his or her own mouth, and gives the victim two puffs of breath big enough to make the chest rise. If the chest does not rise, the individual's head should be repositioned to help ensure the tongue is kept away from the windpipe, then the rescuer should try again to give a breath. Chest compressions should continue with two puffs of breath given for every 50 compressions (two puffs per minute) until help arrives or the victim begins breathing spontaneously.

Purpose

The purpose of CPR is to bring oxygen to the individual's lungs and to keep blood circulating so oxygen gets to every part of the body. When a person is deprived of oxygen, permanent brain damage can begin in as little as four minutes and death can follow only minutes later. When performed quickly enough, CPR can save lives in such emergencies as **heart attack** or sudden cardiac arrest, electric **shock**, near-drowning, drug overdose, and other conditions in which the heart has stopped and there is no breathing.

WWW.BOOKBAZ.IR

Preparation

As CPR is performed in emergency situations, there is no time to prepare the recipient for the procedure. It is necessary to place the recipient on a flat surface facing up before administering compressions.

Training in CPR is the best preparation for the rescuer. Training is not difficult or expensive. The American Heart Association provides CPR instruction for the community in schools, the workplace, and healthcare settings. Courses vary from short programs to teach laypersons the basics of CPR to advanced cardiac **life support** certification for healthcare professionals. CPR is taught as part of many **first aid** courses.

In addition, the American Heart Association has a 22-minute self-directed program called CPR Anytime in an effort to prepare the public and people who would not otherwise attend a CPR course to be able to respond to an emergency with core CPR skills. CPR Anytime does not lead to certification, but research has shown that the program is effective in quickly training the lay public and could prove to be a valuable tool in increasing the overall number of CPR-prepared individuals.

Training and certification

Local medical personnel, staff at hospitals and fire departments, and members of the American Heart Association teach CPR courses for the community, for students, and people at work. There are also extensive courses for allied health professionals. Courses vary from short programs to teach laypersons the basics of CPR to advanced cardiac life support certification for healthcare professionals. Certification must be renewed on a regular basis by taking a refresher course.

Successful CPR is a life-saving procedure. It can restore breathing and circulation in the individual. Medical attention is required immediately even if successful CPR has been performed and the individual is breathing freely.

Precautions

Rescuers should follow these rules:

- Do not leave the individual alone.
- Do not give the individual anything to eat or drink.
- Avoid moving the individual's head or neck if spinal injury is a possibility. To check for breathing when spinal injury is suspected, the rescuer should only listen for breath by the individual's mouth and watch the chest for movement.
- Do not place a pillow under the individual's head.

KEY TERMS

Apnea—A period of no breathing, sometimes sudden, sometimes prolonged.

Arrest—A sudden stopping of the function of a body organ, such as no breathing (respiratory arrest) or no beating of the heart (cardiac arrest).

Cardiopulmonary—Involving both heart and lungs.

Circulation—The passage of blood and delivery of oxygen through the veins and arteries of the body.

Respiratory—Referring to breathing in and breathing out and the function of the lungs.

Resuscitation—Reviving an unconscious person or restoring breathing.

Aftercare

When CPR is initiated, emergency responders have ideally already been notified and are on the way to the scene. It is important to stay with the affected person and continue CPR until breathing and circulation are restored and/or emergency medical personnel arrive. When emergency personnel assume care of the individual, the person who initially provided CPR can often be helpful by providing information to emergency responders.

Risks

Minor injuries such as bruising can occur with chest compressions. Sometimes chest compressions can result in one or more breaks in the ribs and accompanying damage to internal organs, especially in young children, the elderly, and debilitated persons. The American Heart Association states, however, that in the event of a suspected cardiac arrest, even CPR performed by an untrained bystander who receives instructions from an emergency dispatcher is more beneficial than the risk of injury in a person who is actually not in cardiac arrest.

Prevention

People with serious health conditions can follow these general guidelines:

- Risk factors that contribute to heart disease should be reduced or eliminated. People can reduce risks if they stop smoking, lower blood pressure and cholesterol, lose excess weight, and reduce stress.
- Illegal recreational drugs should not be used.

- Seeing a doctor regularly and being aware of any disease conditions or risk factors can help prevent or complicate illness, as can seeking and following the doctor's advice about diet and exercise.

Cardioversion

Definition

Cardioversion refers to the process of restoring the heart's normal rhythm either by applying a controlled electric **shock** to the exterior of the chest or by giving certain medications. The first type is called synchronized electrical cardioversion; the second is called pharmacologic or chemical cardioversion. Abnormal heart rhythms are called **arrhythmias** or dysrhythmias.

Purpose

Cardioversion is used to treat many types of fast and/or irregular heart rhythms. When the heart beats too fast, blood no longer circulates effectively in the body. Most often, cardioversion is used to treat **atrial fibrillation** or **atrial flutter**. It helps return the heart to its normal rhythm so that the heart can pump more efficiently.

Life-saving cardioversion can be used to treat **ventricular tachycardia** and **ventricular fibrillation**; implantable cardioverter-defibrillators (ICDs) are designed to treat these two conditions.

Demographics

Abnormal heart rhythms are slightly more common in men than in women, and the prevalence of abnormal heart rhythms, especially atrial fibrillation, increases with age. Atrial fibrillation is relatively uncommon in people under age 20 but affects 5% of the American population over 65 and 8% of the population over 80. It is responsible for 15–25% of all strokes.

Description

Heart doctors (cardiologists) specially trained in cardioversion (called electrophysiologists) should perform this procedure. To find a heart rhythm specialist or an electrophysiologist, patients can contact the Heart Rhythm Society (formerly the North American Society of Pacing and Electrophysiology). Cardioversion usually takes place in the hospital setting in a special lab called the electrophysiology (EP) laboratory. It may also be performed in an intensive care unit, recovery room, or other special procedure room.

Synchronized electrical cardioversion

Elective synchronized electrical cardioversion is usually scheduled ahead of time. After arriving at the hospital, the patient will have an intravenous (IV) catheter placed in the arm to deliver medications and fluids. Oxygen may be given through a face mask.

In some people, a test called a transesophageal echocardiogram (TEE) may need to be performed before the cardioversion to make sure there are no **blood clots** in the heart.

A short-acting general anesthetic will be given through the IV to put the patient to sleep. During the five or ten minutes of **anesthesia**, an electric shock is delivered through paddles or patches placed on the exterior of the chest and sometimes on the back. It may be necessary for the doctor to administer the shock two or three times to stop the abnormal heartbeat and allow the heart to resume a normal rhythm. During the procedure, the patient's breathing, blood pressure, and heart rhythm are continuously monitored.

Pharmacologic cardioversion

Pharmacologic, or chemical, cardioversion is a less immediate method of restoring normal heart rhythm, and is somewhat less effective than electrical cardioversion, having a success rate between 60% and 80%. It has the advantage of being simpler and

WWW.BOOKBAZ.IR

KEY TERMS

Ablation—The removal or destruction of tissue.

Ablation therapy—A procedure used to treat arrhythmias, especially atrial fibrillation. During the procedure, a catheter (small flexible tube) is inserted into a vein and threaded to the heart. High-frequency electrical energy is delivered through the catheter to disconnect the pathway causing the abnormal heart rhythm in the heart.

Ambulatory monitors—Small portable electrocardiograph machines that record the heart's rhythm. Ambulatory monitors include the Holter monitor, loop recorder, and transtelephonic transmitter. Each type of monitor has specific features related to the length of recording time and the ability to send the recordings over the phone.

Antiarrhythmic—Medication used to treat abnormal heart rhythms.

Anticoagulant—A medication, also called a "blood thinner," that prevents blood from clotting. This type of medication is used for people at risk of stroke or blood clots.

Arrhythmia—An irregular heart rhythm.

Atria (singular, atrium)—The right and left upper chambers of the heart.

Atrial fibrillation—A condition in which the upper chamber of the heart quivers instead of pumping in an organized way.

Atrial flutter—A rapid pulsation of the upper chambers of the heart that interferes with normal heart function. Atrial flutter is usually more organized and regular than atrial fibrillation, although it often converts to atrial fibrillation. Atrial flutter occurs most often in people with heart disease and in the first week after heart surgery.

Cardiac catheterization—An invasive procedure used to create x-ray images of the coronary arteries, heart chambers and valves. During the procedure, a catheter is inserted into an artery in the groin or arm and is guided to the heart. Contrast material (dye) is injected into the catheter to produce the x-ray images.

Echocardiogram—An imaging procedure used to create a picture of the heart's movement, valves and chambers. The test uses high-frequency sound waves that come from a hand wand placed on the chest. Echocardiogram may be used in combination with Doppler ultrasound to evaluate the blood flow across the heart's valves.

Electrocardiogram (ECG, EKG)—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

Electrophysiology study (EPS)—A test that evaluates the electrical activity within the heart. The test is used to help determine the cause of the abnormal heart rhythm and find the best treatment. During the test, the doctor may safely reproduce the abnormal heart rhythm and give the patient medications to determine which medication works best to control the abnormal heart rhythm.

Head-upright tilt table test—A test used to determine the cause of fainting spells. During the test, the patient is tilted at different angles on a special table for a period of time. During the test, the patient's heart rhythm, blood pressure and other measurements are evaluated with changes in position.

more convenient, particularly for patients who are afraid of electrical devices. The patient does not need to undergo anesthesia and can receive the drugs immediately after eating; there is no need to fast for several hours.

There are two basic groups of drugs given in pharmacologic cardioversion: those given to control the heart rate and those given to normalize the heart rhythm. The first group includes such medications as **digoxin** (Lanoxin), diltiazem (Cardizem), verapamil (Calan), esmolol (Brevibloc), metoprolol (Lopressor), and propranolol (Inderal). These drugs may be given either intravenously or orally. With the exception of digoxin, which takes about 30 minutes to take effect, these drugs begin to work in five to seven minutes.

Drugs given to normalize the heart rhythm are called antiarrhythmics. Quinidine (Quinaglute), the oldest drug in this group, is given by mouth, while procainamide, propafenone (Rythmol), flecainide (Tambocor), amiodarone (Cordarone), sotalol (Betapace), dofetilide (Tikosyn), and ibutilide (Corvert) may be given intravenously or orally. Unlike the drugs given to control the heart rate, these medications take longer to work, one hour for procainamide and ibutilide, and three to eight hours for the others. These drugs should be administered in a hospital

Implantable cardioverter-defibrillator (ICD)—An electronic device that is surgically placed to constantly monitor the patient's heart rate and rhythm. If a very fast abnormal heart rate is detected, the device delivers electrical energy to the heart to beat in a normal rhythm again.

Maze procedure—A surgical procedure used to treat atrial fibrillation. During the procedure, precise incisions are made in the right and left atria to interrupt the conduction of abnormal impulses. When the heart heals, scar tissue forms and the abnormal electrical impulses are blocked from traveling through the heart.

Nuclear imaging—Method of producing images by detecting radiation from different parts of the body after a radioactive tracer material is administered.

Pacemaker—A small electronic device implanted under the skin. This device sends electrical impulses to the heart to maintain a suitable heart rate and prevent slow heart rates.

Pharmacologic cardioversion—The use of medications to restore normal heart rhythm. It is also called chemical cardioversion.

Pulmonary vein isolation—A surgical procedure used to treat atrial fibrillation. During the procedure, a radio frequency probe, microwave probe, or cryoprobe is inserted and, under direct vision, used to create lesion lines in the heart to interrupt the conduction of abnormal impulses.

Stress test—A test used to determine how the heart responds to stress. It usually involves walking on a treadmill or riding a stationary bike at increasing levels of difficulty, while the electrocardiogram, heart rate and blood pressure are monitored. If the patient is unable to walk on a treadmill or ride a stationary bike, medications may be used to produce similar results.

Synchronized electrical cardioversion—The term used to describe cardioversion by the application of a controlled electric shock to the patient's chest.

Transesophageal echocardiogram (TEE)—An invasive imaging procedure used to create a picture of the heart's movement, valves, and chambers. The test uses high-frequency sound waves that come from a small transducer passed down the patient's throat. TEE may be used in combination with Doppler ultrasound to evaluate the blood flow across the heart's valves.

Ventricles—The lower, pumping chambers of the heart. The heart has two ventricles: the right and the left ventricle.

Ventricular fibrillation—An erratic, disorganized firing of impulses from the ventricles, the lower chambers of the heart. The ventricles quiver instead of pumping in an organized way, preventing blood from pumping through the body. Ventricular fibrillation is a medical emergency that must be treated with cardiopulmonary resuscitation (CPR) and defibrillation as soon as possible.

Ventricular tachycardia—A rapid heart beat, usually over 100 beats per minute. Ventricular tachycardia originates from the lower chambers of the heart (ventricles). The rapid rate prevents the heart from filling adequately with blood, so less blood is able to pump through the body. Ventricular tachycardia can be a serious type of arrhythmia and may be associated with more symptoms.

setting where the patient can be monitored. Dofetilide can be prescribed only by physicians who have had special training in the risks and side effects of the drug.

Diagnosis

A doctor may be able to detect an irregular heart beat during a physical exam by taking the patient's pulse. In addition, the diagnosis may be based upon the presence of certain symptoms, including:

- palpitations (feeling of skipped heart beats or fluttering in the chest)
- pounding in the chest
- shortness of breath
- chest discomfort
- fainting
- dizziness or feeling light-headed
- weakness or fatigue

Not everyone with abnormal heart rhythms will experience symptoms, so the condition may be discovered upon examination for another medical condition.

WWW.BOOKBAZ.IR

Diagnostic tests

Tests used to diagnose an abnormal heart rhythm or determine its cause include:

- blood tests
- chest x-rays
- electrocardiogram
- ambulatory monitors such as the Holter monitor, loop recorder, and transtelephonic transmitter
- stress test
- echocardiogram
- cardiac catheterization
- electrophysiology study (EPS)
- head-upright tilt table test
- nuclear medicine test, such as a MUGA scan (multiple-gated acquisition)

Preparation

Medication to thin the blood (blood thinner or anticoagulant) is usually given for at least three weeks before elective cardioversion. The patient should take all usual medications as prescribed, unless other instructions have been given. Patients who take diabetes medications or anticoagulants should ask their doctor for specific instructions.

The patient should not eat or drink anything for six to eight hours before the procedure.

It is advisable to arrange for transportation home, because drowsiness may last several hours and driving is not permitted after the procedure. The patient is also advised not to apply any lotion or ointments to the chest or back before the procedure.

Aftercare

The patient generally wakes quickly after the procedure. Medical personnel will monitor the patient's heart rhythm for a few hours, after which the patient is usually sent home. The patient should not drive home; driving is not permitted for 24 hours after the procedure.

Medications

The doctor may prescribe anti-arrhythmic medications (such as beta-blockers, digitalis, or **calcium channel blockers**) to prevent the abnormal heart rhythm from returning.

Some patients may be prescribed anticoagulant medication, such as warfarin and **aspirin**, to reduce the risk of blood clots.

The medications prescribed may be adjusted over time to determine the best dosage and type of medication so the abnormal heart rhythm is adequately controlled.

Discomfort

Some chest wall discomfort may be present for a few days after the procedure. The doctor may recommend that the patient take an over-the-counter **pain** reliever such as ibuprofen to relieve discomfort. Skin irritation may also be present after the procedure. Skin lotion or ointment can be used to relieve irritation.

Results

About 90% of cardioversions are successful in restoring the normal heart rhythm safely and preventing further symptoms, at least temporarily.

Risks

Cardioverters have been in use for many years and the risks are few. The unlikely risks that remain include those instances when the device delivers greater or lesser power than expected or when the power setting and control knobs are not set correctly. Unfortunately, in about 50% of cases, the heart prefers its abnormal rhythm and reverts to it within one year, despite cardioversion. Cardioversion can be repeated for some patients whose abnormal heart rhythm returns.

Alternatives

Atrial fibrillation and atrial flutter often revert to normal rhythms without the need for cardioversion. Healthcare providers usually try to correct the heart rhythm with medication or recommend lifestyle changes before recommending electrical cardioversion.

Lifestyle changes often recommended to treat abnormal heart rhythms include:

- quitting smoking
- avoiding activities that prompt the symptoms of abnormal heart rhythms
- limiting alcohol intake
- limiting or not using caffeine (caffeine products may produce more symptoms in some people with abnormal heart rhythms)
- avoiding medications containing stimulants, such as some cough and cold remedies (these medications contain ingredients that may cause abnormal heart rhythms)

If cardioversion is not successful in restoring the normal heart rhythm, other treatments for abnormal heart rhythms are considered. These include an implantable cardioverter-defibrillator (ICD). Since first approved by the U.S. Food and Drug Administration (FDA) in 1985, ICDs have been continually improved. Current models are much smaller and easier to implant than the early ICDs, can be programmed to deliver low-energy or high-energy shocks, and have batteries that last as long as six years. Originally considered a treatment of last resort, ICDs are now considered first-line therapy for some abnormal heart rhythms. The chief drawback of ICDs is the **anxiety** some patients feel about the possibility of the device's firing (emitting a shock).

Other treatments for abnormal heart rhythms include permanent **pacemakers**, ablation therapy, and heart surgery—including the Maze procedure and the pulmonary vein isolation procedure.

Morbidity and mortality rates

Controlling a patient's heart rate is as important as controlling the patient's heart rhythm to prevent death and complications from cardiovascular causes. Anticoagulant therapy is important to reduce the risk of **stroke** and is appropriate therapy for patients who have recurring, persistent atrial fibrillation even after they were treated with cardioversion. In patients who did not receive anticoagulant therapy after cardioversion, there was a reported 2.4% increase of embolic events (such as stroke or blood clots) even though there were no signs of these events prior to the procedure.

Carotid sinus massage

Definition

Carotid sinus massage involves rubbing the large part of the arterial wall at the point where the common carotid artery, located in the neck, divides into its two main branches.

WWW.BOOKBAZ.IR

KEY TERMS

Angina pectoris—Chest pain usually caused by a lack of oxygen in the heart muscle.

Arrhythmia—Any deviation from a normal heart beat.

Atrial fibrillation—A condition in which the upper chamber of the heart quivers instead of pumping in an organized way.

Atrial flutter—Rapid, inefficient contraction of the upper chamber of the heart.

Carotid artery—One of the major arteries supplying blood to the head and neck.

Tachycardia—A rapid heart beat, usually over 100 beats per minute.

Purpose

Sinus, in this case, means an area in a blood vessel that is bigger than the rest of the vessel. This is a normal dilation of the vessel. Located in the neck just below the angle of the jaw, the carotid sinus sits above the point where the carotid artery divides into its two main branches. Rubbing the carotid sinus stimulates an area in the artery wall that contains nerve endings. These nerves respond to changes in blood pressure and are capable of slowing the heart rate. The response to this simple procedure often slows a rapid heart rate (for example, **atrial flutter** or atrial tachycardia) and can provide important diagnostic information to the physician.

Description

The patient will be asked to lie down, with the neck fully extended and the head turned away from the side being massaged. While watching an electrocardiogram monitor, the doctor will gently touch the carotid sinus. If there is no change in the heart rate on the monitor, the pressure is applied more firmly with a gentle rotating motion. After massaging one side of the neck, the massage will be repeated on the other side. Both sides of the neck are never massaged at the same time.

Preparation

No special preparation is needed for carotid sinus massage.

Aftercare

No aftercare is required.

Risks

The physician must be sure there is no evidence of blockage in the carotid artery before performing the procedure. Massage in a blocked area might cause a clot to break loose and cause a **stroke**.

Results

Carotid sinus massage will slow the heart rate during episodes of atrial flutter, fibrillation, and some tachycardias. It has been known to stop the arrhythmia completely. If the procedure is being done to help diagnose **angina** pectoris, massaging the carotid sinus may make the discomfort go away.

Carpal tunnel syndrome

Definition

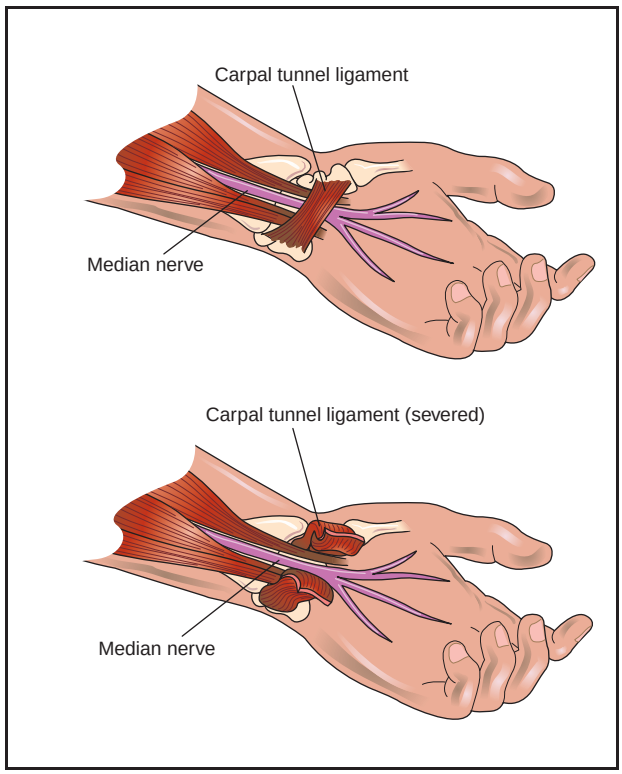
Carpal tunnel syndrome is a disorder caused by compression at the wrist of the median nerve supplying the hand, causing **numbness and tingling**.

Description

The carpal tunnel is an area in the wrist where the bones and ligaments create a small passageway for the median nerve. The median nerve is responsible for both sensation and movement in the hand, in particular the thumb and first three fingers. When the median nerve is compressed, an individual's hand will feel numb.

Demographics

Women are three times as likely as men to suffer from carpal tunnel syndrome, and women between the ages of 45 and 64 are most likely to be affected by the condition. Research has demonstrated that carpal tunnel syndrome is a very significant cause of missed work



The most severe cases of carpal tunnel syndrome may require surgery to decrease the compression of the median nerve and restore its normal function. This procedure involves severing the ligament that crosses the wrist, thus allowing the median nerve more room and decreasing compression. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

days due to **pain**. At any one time, about 5percnt; of Americans suffer from this condition.

Causes and symptoms

Compression of the median nerve in the wrist can occur during a number of different conditions, particularly those conditions which lead to changes in fluid accumulation throughout the body. Because the area of the wrist through which the median nerve passes is very narrow, any swelling in the area will lead to pressure on the median nerve. This pressure will ultimately interfere with the nerve's ability to function normally. **Pregnancy**, **obesity**, arthritis, certain thyroid conditions, diabetes, and certain pituitary abnormalities all predispose individuals to carpal tunnel syndrome. Other conditions which increase the risk for carpal tunnel syndrome are some forms of arthritis and various injuries to the arm and wrist (including **fractures**, sprains, and **dislocations**). Furthermore, activities which cause individuals to repeatedly bend the wrist inward toward the forearm can predispose these people to carpal tunnel syndrome. Jobs that require repeated strong wrist motions carry a relatively high risk of carpal tunnel syndrome. Injuries of this type are referred to as repetitive-motion injuries and are more frequent among secretaries doing a lot of typing, people working at computer keyboards or cash registers, factory workers, and some musicians.

Symptoms of carpal tunnel syndrome include numbness, burning, tingling, and a prickly pin-like sensation over the palm surface of the hand and into the thumb, forefinger, middle finger, and half of the ring finger. Some individuals notice a shooting pain from the wrist up the arm or down into the hand and fingers. With continued median nerve compression, individuals may begin to experience muscle weakness, making it difficult to open jars and hold objects with the affected hand. Eventually, the muscles of the hand served by the median nerve may begin to grow noticeably smaller (atrophy), especially the fleshy part of the thumb. Left untreated, carpal tunnel syndrome may eventually result in permanent weakness, loss of sensation, or even **paralysis** of the thumb and fingers of the affected hand.

Diagnosis

The diagnosis of carpal tunnel syndrome is made in part by checking to see whether the patient's symptoms can be brought on by holding his or her hand in position with wrist bent for about a minute. Wrist x rays are often taken to rule out the possibility of a tumor or fracture that causing compression of the median nerve. A physician examining a patient suspected of having carpal tunnel syndrome will perform a variety of simple tests to measure muscle strength and sensation in the affected hand and arm. Further testing might include electromyographic or nerve conduction velocity testing to determine the exact severity of nerve damage. These tests involve stimulating the median nerve with electricity and measuring the resulting speed and strength of the muscle response, as well as recording speed of nerve transmission across the carpal tunnel. Further testing may include **electromyography** and nerve conduction studies. Nerve conduction studies measure the speed and integrity of the median nerve across the carpal tunnel and electromyography, or EMG, measures the electrical response of the muscles innervated by the median nerve.

Treatment

Carpal tunnel syndrome is initially treated with splints, which support the wrist and prevent it from flexing inward into the position that exacerbates

WWW.BOOKBAZ.IR

KEY TERMS

Carpal tunnel—A passageway in the wrist, created by the bones and ligaments of the wrist, through which the median nerve passes.

Electromyography (EMG)—A type of test in which a nerve's function is tested by stimulating the nerve with electricity and then measuring the speed and strength of the corresponding muscle's response.

Median nerve—A nerve that runs through the wrist and into the hand. It provides sensation and some movement to the hand, the thumb, the index finger, the middle finger, and half of the ring finger.

median nerve compression. Some people get significant relief by wearing such splints to sleep at night, whereas others need to wear the splints all day, especially if they are performing jobs that **stress** the wrist. Ibuprofen or other **nonsteroidal anti-inflammatory drugs** may be prescribed to decrease pain and swelling. When carpal tunnel syndrome is more advanced, injection of **steroids** into the wrist to decrease inflammation may be necessary.

The most severe cases of carpal tunnel syndrome may require surgery to decrease the compression of the median nerve and restore its normal function. Such a repair involves cutting the ligament that crosses the wrist, thus allowing the median nerve more room and decreasing compression. This surgery is done almost exclusively on an outpatient basis and is often performed without the patient having to be made unconscious. Careful injection of numbing medicines (local **anesthesia**) or nerve blocks (the injection of anesthetics directly into the nerve) create sufficient numbness to allow the surgery to be performed painlessly, without the risks associated with general anesthesia. Recovery from this type of surgery is usually quick and without complications.

Prognosis

Without treatment, continued pressure on the median nerve puts individuals at risk for permanent disability in the affected hand. Most people are able to control the symptoms of carpal tunnel syndrome with splinting and anti-inflammatory agents. For those who go on to require surgery, about 95% will have complete cessation of symptoms.

Prevention

Prevention is generally aimed at becoming aware of the repetitive motions that one must make which could put the wrist into a bent position. People who must work long hours at a computer keyboard, for example, may need to take advantage of recent advances in ergonomics, which try to position the keyboard and computer components in a way that increases efficiency and decreases stress. Early use of a splint may also be helpful for people whose jobs increase the risk of carpal tunnel syndrome.

Cataract surgery

Definition

Cataract surgery is a procedure performed to remove a cloudy (natural) lens from the eye; usually an intraocular (artificial) lens is implanted at the same time. The removed lens, sometimes also called a crystalline lens, is called a cataract because the originally clear lens has turned cloudy. An ophthalmologist (commonly called an eye surgeon) usually performs

such surgeries on an outpatient basis within a surgical center, hospital, or other professional medical facility. The commonly performed procedure, which takes less than an hour, is generally safe and nearly risk free.

Demographics

Nearly all cataract surgeries are performed on older people. As the eyes age, **cataracts** form on the lens of the eyes, which cause blurry vision, difficulties looking at bright lights, and other such vision problems. According to the National Institutes of Health, over 50% of people in the United States over the age of 80 years have a cataract or have had cataract surgery. Normally, people will have cataract surgery when the eyes degrade enough so that it is increasingly difficult to carry out daily activities of life. Often times, people, especially elderly adults, have other eye problems, such as **macular degeneration**, which are difficult to treat when cataracts are present. In such cases, it is often advisable to have the cataracts removed.

Purpose

The purpose of cataract surgery is to restore clear vision. It is indicated when cloudy vision due to cataracts has progressed to such an extent that it interferes with normal daily activities. Other symptoms of cataracts include colors that fade, excessive glare, inability to see well at night, double vision, and numerous changes in vision prescriptions (for **eye glasses** or contacts). It is one of the most commonly performed surgical procedures in the world.

Precautions

Cataract surgery is not performed on both eyes at once. To avoid risking blindness in both eyes in the event of infection or other catastrophe, the first eye is allowed to heal before the cataract is removed from the second eye.

The presence of cataracts can mask additional eye problems, such as retinal damage, that neither doctors nor patients are aware of prior to surgery. Since such conditions will continue to impair sight after cataract removal if they are not identified and treated, the eventual outcome of cataract surgery will depend on the outcome of other problems.

In 1997 and 1998, evidence that cataract surgery can contribute to the progression of age-related macular degeneration (ARMD) was published. ARMD is the degeneration of the central part of the retina. However, as of 2014, studies have not shown such a conclusive relationship. Whether cataract surgery contributes to the progression of ARMD is still up to debate in the medical community. Accordingly, ARMD patients with cataracts must weigh the possible risks of the loss of central vision, within four or five years, against short-term improvement. When an ARMD patient chooses cataract surgery, the surgeon should shield the retina against bright light to protect it from possible light-induced damage during surgery and install an intraocular lens capable of absorbing ultraviolet and blue light, which seem to do the most damage.

Description

Just before the start of the surgery, eye drops are placed in the eye to dilate the pupil. Local anesthetics are provided to de-sensitive (numb) the area around the eye. A sedative may be provided for anxious patients so they can relax. The patient will remain awake during the surgery but may feel sleepy.

There are two types of cataract surgery: intracapsular and extracapsular. Intracapsular surgery is the removal of both the lens and the thin capsule that surround the lens. This type of surgery was common before 1980, but it has since been displaced by extracapsular surgery. Removal of the capsule requires a large incision and does not allow comfortable intraocular lens implantation. Thus, people who undergo intracapsular cataract surgery have long recovery periods and have to wear very thick glasses.

Extracapsular cataract surgery is the removal of the lens where the capsule is left in place. Each year in the United States, over a million cataracts are removed this way. Physicians and researchers continue to improve cataract surgery methods. Research from France in 2003 said that cataract removal and nonpenetrating **glaucoma** surgery can be combined in glaucoma patients.

There are two methods for extracapsular cataract surgery. The usual technique is phacoemulsification. A tiny incision (about 0.12-inch, or 3-millimeter, long) is made next to the cornea (the eye's outer covering) in the front of the eye, and an ultrasonic probe is used to break up (emulsify) the cataract into minute pieces, which are then removed by suction. Stitches may or may not be used to close the small incision point.

When the lens is too hard to be emulsified ultrasonically, the surgeon will use a slightly different technique called extracapsular extraction, which requires a larger incision. The extracapsular extraction is performed during phacoemulsification. During the process, an incision—one with a length of about 0.37 inch (9 millimeters) long—is made, and the whole lens (without its capsule) is removed through the incision.

WWW.BOOKBAZ.IR

KEY TERMS

Age-related macular degeneration (ARMD)—Degeneration of the macula (the central part of the retina where the rods and cones are most dense) that leads to loss of central vision in people over 60 years of age.

Cataract—Progressive opacity or clouding of an eye lens, which obstructs the passage of light to the retina.

Cornea—Clear outer covering of the front of the eye.

Intraocular lens—Lens made of silicone or plastic placed within the eye; can be corrective.

Retina—Innermost layer at the back of the eye, which contains light receptors, the rods and cones.

In this method, stitches are usually necessary. Both kinds of extracapsular cataract surgery leave the back of the capsule intact, so a silicone or plastic intraocular lens can be stably implanted in about the same location as the original lens.

The surgery takes about 30 to 60 minutes for one eye. Once completed the patient will have a clear, artificial lens implanted into the empty capsule. The implant, called an intraocular lens (IOL), is made of acrylic, plastic, or silicone. There are a variety of different IOLs that can be implanted. Some are flexible, while others rigid. Some are made so they block ultraviolet (UV) radiation, while others function like bifocal or trifocal eye glasses.

Preparation

Patients must have a pre-operation **eye examination**, which will include **ultrasound** analysis to make sure the retina (the innermost layer of the eye, containing the light receptors) is intact and also to measure eye curvature so that a lens with the proper correction can be implanted. The patient also will have a pre-operative **physical examination**. In addition, patients start a course of antibiotic eye drops or ointment the day before surgery. Medications taken by the patient may be stopped under the advice of the surgeon. Such medications include any that may cause increased bleeding during surgery.

About 12 hours before the surgery, the physician may ask you to stop eating or drinking. The medical staff will also ask the patient to arrange for someone to remain at the surgical site to drive the patient home afterwards.

Aftercare

Proper post-operative care is especially important after cataract surgery. Patients will need someone to drive them home after the surgery and should not bend over or lift anything up for a few days after the surgery, or do anything strenuous for about two weeks. The sight through the repaired eye will be blurry over the first few days after surgery as the eye adjusts to the new lens. Patients should refrain from rubbing or pressing the eye, should wear glasses to protect their eye, and should wear a shield while sleeping so the eye will not be rubbed or bumped accidentally.

The patient will usually continue their antibiotic for two to three weeks and will also take anti-inflammatory medication for about the same length of time. If the patient experiences inflammation, redness, or **pain**, they should seek immediate medical treatment to avoid serious complications. If complications do not occur, the patient will normally visit the doctor a few days after the surgery and, then again, after a week and finally after a month.

Any type of after care is not necessary for the intraocular lens itself. It becomes a permanent part of the eye. The eye should be completely healed within eight weeks of the surgery.

Results

Ordinarily, according to the National Institutes of Health, about 95% of patients experience improved visual acuity and improved perception of the vividness of colors, leading to increased abilities in many activities, including reading, needlework, driving, golf, and tennis, for example. This improvement in sight should be apparent within a few days after the surgery. In addition, sometimes implanted corrective lenses eliminate the need for eyeglasses or **contact lenses**. Researchers and manufacturers also continue to work to improve the lenses available in cataract surgeries, so that eventual vision and outcome are improved.

Risks

Cataract surgery itself is quite safe and is almost always treated successfully; over 90% of the time,

complications do not occur. However, complications can occur and should be noted by anyone thinking about cataract surgery. Possible complications include intraocular infection (endophthalmitis), central retinal inflammation (macular **edema**), post-operative glaucoma, **retinal detachment**, bleeding under the retina (choroidal hemorrhage), and tiny lens fragments in the back (vitreous) cavity of the eye, all of which can lead to loss of sight.

If the following symptoms occur, contact your doctor immediately:

- nausea, vomiting, or disproportionate amount of coughing
- loss of vision in the eye
- redness in the eye
- excessive, persistent pain (especially if pain medications are being used)
- flashes of light or floaters (spots) on the front of the eye

An added risk of complications can also occur when other diseases are present. Such diseases may prevent an otherwise successful surgery from being completed satisfactorily. In such cases, vision may not be improved due to diseases present within the body, and especially those diseases of the eyes, such as glaucoma. Consequently, it may be wise to treat such diseases before having cataract surgery.

Since increased use of the phacoemulsification method of cataract surgery, researchers have noted a decline in cases of infection (endophthalmitis). This probably is because injectable intraocular lenses do not make contact with the ocular surface. In 2004, the FDA approved a new capsular tension ring for use in cataract surgery that helps prevent lens dislocation and other possible complications of surgery.

After cataract surgery, some patients develop posterior capsule opacification (PCO). This complication occurs when the back of the lens capsule becomes cloudy and sight is again degraded. However, if this happens, then a procedure called yttrium-aluminum-garnet (YAG) laser capsulotomy can be performed. The procedure allows light to pass through the clouded capsule, which solves the problem.

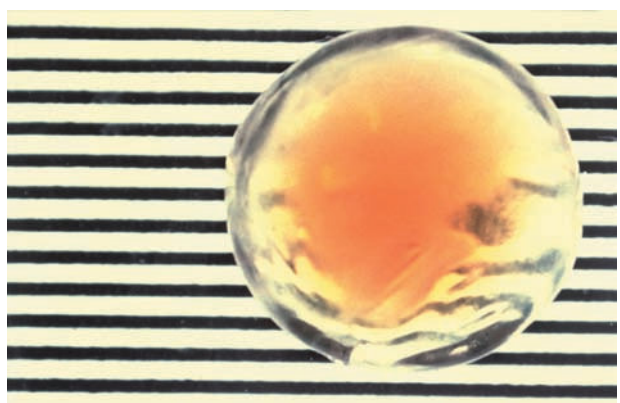
Cataracts

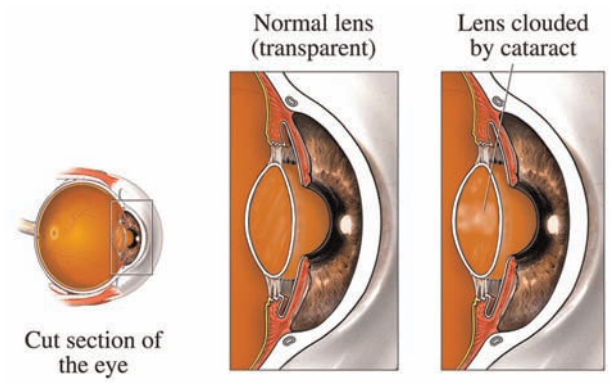
Definition

A cataract is a cloudiness or opacity in the normally transparent crystalline lens of the eye. This cloudiness can cause a decrease in vision and may lead to eventual blindness.



A dense cataract on lens of eye. *(© Margaret Cubberly/ Phototake.—All rights reserved.)*

WWW.BOOKBAZ.IR



Normal eye compared to an eye with a cataract. *(© Nucleus Medical Art, Inc/Alamy.)*

Description

The human eye has several parts. The outer layer of the eyeball consists of a transparent dome-shaped cornea and an opaque, white sclera. The cornea and sclera help protect the eye. The next layer includes the iris, pupil, and ciliary body. The iris is the colored part of the eye and the pupil is the small dark round hole in the middle of the iris. The pupil and iris allow light into the eye. The ciliary body contains muscles that help in the eye's focusing ability. The lens lies behind the pupil and iris. It is covered by a cellophane-like capsule. The lens is normally transparent, elliptical in shape, and somewhat elastic. This elasticity allows the lens to focus on both near and far objects. The lens is attached to the ciliary body by fibers (zonules of Zinn). Muscles in the ciliary body act on the zonules, which then change the shape of the lens. This process is called accommodation—the lens focuses images to help make vision clear. As people age, the lens hardens and changes shape less easily. As a result, the accommodation process becomes more difficult, making it harder to see things up close. This generally occurs around the age of 40 and continues until about age 65. The condition is called **presbyopia**. It is a normal condition of **aging**, generally resulting in the need for reading glasses.

The lens is made up of approximately 35% protein and 65% water. As people age, degenerative changes in the lens's proteins occur. Changes in the proteins, water content, enzymes, and other chemicals are some of the reasons for the formation of a cataract.

The major areas of the lens are the nucleus, the cortex, and the capsule. The nucleus is in the center of the lens, the cortex surrounds the nucleus, and the capsule is the outer layer. Opacities can occur in any area of the lens. Cataracts, then, can be classified according to location (nuclear, cortical, or posterior subcapular cataracts). The density and location of the cataract determine the amount of vision affected. If the cataract forms in the area of the lens directly behind the pupil, vision may be significantly impaired. A cataract that occurs on the outer edges or side of the lens will create less of a visual problem.

Cataracts in the elderly are so common that they are thought to be a normal part of the aging process. Between the ages of 52 and 64, there is a 50% chance of having a cataract, while at least 70% of those 70 and older are affected. In 2004, it was revealed that blacks are twice as likely to develop cataracts as whites. Cataracts associated with aging (senile or age-related cataracts) most often occur in both eyes, with each cataract progressing at a different rate. Initially, cataracts may not affect vision. If the cataract remains small or at the periphery of the lens, the visual changes may be minor.

Cataracts that occur in people other than the elderly are much less common. Congenital cataracts occur very rarely in newborns. Genetic defects or an infection or disease in the mother during **pregnancy** are among the causes of congenital cataracts. Traumatic cataracts may develop after a foreign body or **trauma** injures the lens or eye. Systemic illnesses, such as diabetes, may result in cataracts. Cataracts can also occur secondary to other eye diseases—for example, an inflammation of the inner layer of the eye (**uveitis**) or **glaucoma**. Such cataracts are called complicated cataracts. Toxic cataracts result from chemical toxicity, such as steroid use. Cataracts can also result from exposure to the sun's ultraviolet (UV) rays.

Causes and symptoms

Recent studies have been conducted to try to determine whether diet or the use of **vitamins** might have an effect on the formation of cataracts in older people. The results have been mixed, with some studies finding a connection and other studies finding none. Much interest has been focused on the use of antioxidant supplements as a protection against cataracts. Antioxidant vitamins such as vitamins A, C, E, and beta-carotene help the body clean-up oxygen-free radicals. Some vitamins are marketed specifically for the eyes. Patients should speak to their doctors about the use of such vitamins.

Smoking and alcohol intake have been implicated in cataract formation. Some studies have determined that a diet high in fat will increase the likelihood of cataract formation, while an increase in foods rich in **antioxidants** will reduce the incidence. More research

is needed to determine if diet, smoking, alcohol consumption, or vitamins have any connection to the formation of cataracts.

There are several common symptoms of cataracts:

- gradual, painless onset of blurry, filmy, or fuzzy vision
- poor central vision
- frequent changes in eyeglass prescription
- changes in color vision
- increased glare from lights, especially oncoming headlights when driving at night
- "second sight" improvement in near vision (no longer needing reading glasses), but a decrease in distance vision
- poor vision in sunlight
- presence of a milky whiteness in the pupil as the cataract progresses.

Diagnosis

Both ophthalmologists and optometrists may detect and monitor cataract growth and prescribe prescription lenses for visual deficits. However, only an ophthalmologist can perform cataract extraction.

Cataracts are easily diagnosed from the reporting of symptoms, a visual acuity exam using an eye chart, and by examination of the eye itself. Shining a penlight into the pupil may reveal opacities or a color change of the lens even before visual symptoms have developed. An instrument called a slit lamp is basically a large microscope. This lets the doctor examine the front of the eye and the lens. The slit lamp helps the doctor determine the location of the cataract.

Some other diagnostic tests may be used to determine if cataracts are present or how well the patient may potentially see after surgery. These include a glare test, potential vision test, and contrast sensitivity test.

Treatment

For cataracts that cause no symptoms or only minor visual changes, no treatment may be necessary. Continued monitoring and assessment of the cataract is needed by an ophthalmologist or optometrist at scheduled office visits. Increased strength in prescription eyeglasses or **contact lenses** may be helpful. This may be all that is required if the cataract does not reduce the patient's quality of life.

Cataract surgery—the only option for patients whose cataracts interfere with vision to the extent of affecting their daily lives—is the most frequently performed surgery in the United States. It generally improves vision in over 90% of patients. Some people have heard that a cataract should be "ripe" before being removed. A cataract is considered ripe or mature when the lens is completely opaque. Most cataracts are removed before they reach this stage. Sometimes cataracts need to be removed so that the doctor can examine the back of the eye more carefully. This is important in patients with diseases that may affect the eye. If cataracts are present in both eyes, only one eye at a time should be operated on. Healing occurs in the first eye before the second cataract is removed, sometimes as early as the following week. A final eyeglass prescription is usually given about four to six weeks after surgery. Patients will still need reading glasses. The overall health of the patient needs to be considered in making the decision to operate. However, age alone need not preclude effective surgical treatment of cataracts. People in their nineties can have successful return of vision after **cataract surgery**.

Surgery to remove cataracts is generally an outpatient procedure. A local anesthetic is used and the procedure lasts about one hour. Removal of the cloudy lens can be done by several different procedures. The three types of cataract surgery available are:

- Extracapsular cataract extraction. This type of cataract extraction is the most common. The lens and the front portion of the capsule are removed. The back part of the capsule remains, providing strength to the eye.
- Intracapsular cataract extraction. The lens and the entire capsule are removed. This method carries an increased risk for detachment of the retina and swelling after surgery. It is rarely used.
- Phacoemulsification. This type of extracapsular extraction needs a very small incision, resulting in faster healing. Ultrasonic vibration is applied to the lens to break it up into very small pieces which are then aspirated out of the eye with suction by the ophthalmologist. A new liquid technique that its inventor says may one day replace ultrasound has been invented, but has not yet been proven in clinical trials.

A replacement lens is usually inserted at the time of the surgery. A plastic artificial lens called an intraocular lens (IOL) is placed in the remaining posterior lens capsule of the eye. When the intracapsular extraction method is used, an IOL may be clipped onto the iris. Contact lenses and cataract glasses (aphakic lenses) are prescribed if an IOL was not inserted. A folding IOL is used when phacoemulsification is performed to accommodate the small incision.

WWW.BOOKBAZ.IR

KEY TERMS

Aphakia—Absence of the lens of the eye.

Ciliary body—A structure in the eye that contains muscles that will affect the focusing of the lens.

Glaucoma—Disease of the eye characterized by increased pressure of the fluid inside the eye. Untreated, glaucoma can lead to blindness.

Phacoemulsification—Surgical procedure to remove a cataract using sound waves to disintegrate the lens which is then removed by suction.

Retina—The innermost layer of the eyeball. Images focused onto the retina are then sent to the brain.

Ultraviolet radiation (UV)—Invisible light rays that may be responsible for sunburns, skin cancers, and cataract formation.

Uveitis—Inflammation of the uvea. The uvea is a continuous layer of tissue that consists of the iris, the ciliary body, and the choroid. The uvea lies between the retina and sclera.

Antibiotic drops to prevent infection and **steroids** to reduce inflammation are prescribed after surgery. An eye shield or glasses during the day will protect the eye from injury while it heals. During the night, an eye shield is worn. The patient returns to the doctor the day after surgery for assessment, with several follow-up visits over the next two months to monitor the healing process.

Prognosis

The success rate of cataract extraction is very high, with a good prognosis. A visual acuity of 20/40 or better may be achieved. If an extracapsular cataract extraction was performed, a secondary cataract may develop in the remaining back portion of the capsule. This can occur one to two years after surgery. YAG capsulotomy is most often used for this type of cataract. YAG stands for yttrium aluminum garnet, the name of the laser used for this procedure. This is a painless outpatient procedure and requires no incision. The laser beam makes a small opening in the remaining back part of the capsule, allowing light through.

In a very small percentage (3–5%) of surgical cataract extractions, complications occur. Infections, swelling of the cornea (**edema**), bleeding, **retinal detachment**, and the onset of glaucoma have been reported. Some problems may occur one to two days, or even several weeks, after surgery. Any haziness, redness, decrease in vision, nausea, or **pain** should be reported to the surgeon immediately.

Prevention

Preventive measures emphasize protecting the eyes from UV radiation by wearing glasses with a special coating to protect against UV rays. Dark lenses alone are not sufficient. The lenses must protect against UV light (specifically, UV-A and UV-B). Antioxidants may also provide some protection by reducing free radicals that can damage lens proteins. A healthy diet rich in sources of antioxidants, including citrus fruits, sweet potatoes, carrots, green leafy vegetables, and/or vitamin supplements may be helpful. In 2004, research in England revealed that **nonsteroidal anti-inflammatory drugs** (over-the counter pain killers such as **aspirin**) may help decrease risk of cataracts by as much as 43%. When taking certain medications, such as steroids, more frequent eye exams may be necessary. Patients should speak to their doctors to see if medications may affect their eyes.

Catatonia

Definition

Catatonia is a condition marked by changes in muscle tone or activity associated with a large number of serious mental and physical illnesses. There are two distinct sets of symptoms that are characteristic of this condition. In catatonic stupor the individual experiences a deficit of motor (movement) activity that can render him/her motionless. Catatonic excitement, or excessive movement, is associated with violent behavior directed toward oneself or others.

Features of catatonia may also be seen in Neuroleptic Malignant Syndrome (NMS) which is an uncommon (but potentially lethal) reaction to some medications used to treat major mental illnesses. NMS is considered a medical emergency since 25% of untreated cases result in death. Catatonia can also be present in individuals suffering from a number of other physical and emotional conditions such as drug intoxication, depression, and **schizophrenia**. It is most commonly associated with **mood disorders**.

Description

In catatonic stupor, motor activity may be reduced to zero. Individuals avoid bathing and grooming, make little or no eye contact with others, may be mute and rigid, and initiate no social behaviors. In catatonic excitement the individual is extremely hyperactive although the activity seems to have no purpose. Violence toward him/herself or others may also be seen.

NMS is observed as a dangerous side effect associated with certain neuroleptic (antipsychotic) drugs such as haloperidol (Haldol). It comes on suddenly and is characterized by stiffening of the muscles, **fever**, confusion, and heavy sweating.

Catatonia can also be categorized as intrinsic or extrinsic. If the condition has an identifiable cause, it is designated as extrinsic. If no cause can be determined following **physical examination**, laboratory testing, and history taking, the illness is considered to be intrinsic.

Causes and symptoms

The causes of catatonia are largely unknown although research indicates that brain structure and function are altered in this condition. While this and other information point to a physical cause, none has yet been proven. A variety of medical conditions also may lead to catatonia including head **trauma**, cerebrovascular disease, encephalitis, and certain metabolic disorders. NMS is an adverse side effect of certain **antipsychotic drugs**.

A variety of symptoms are associated with catatonia. Among the more common are echopraxia (imitation of the gestures of others) and echolalia (parrot-like repetition of words spoken by others). Other signs and symptoms include violence directed toward him/herself, the assumption of inappropriate posture, selective **mutism**, negativism, facial grimaces, and animal-like noises.

Catatonic stupor is marked by immobility and a behavior known as *cerea flexibilitas* (waxy flexibility) in which the individual can be made to assume bizarre (and sometimes painful) postures that they will maintain for extended periods of time. The individual may become dehydrated and malnourished because food and liquids are refused. In extreme situations such individuals must be fed through a tube. Catatonic excitement is characterized by hyperactivity and violence; the individual may harm him/herself or others. On rare occasions, **isolation** or restraint may be needed to ensure the individual's safety and the safety of others.

Diagnosis

Recognition of catatonia is made on the basis of specific movement symptoms. These include odd ways of walking such as walking on tiptoes or ritualistic pacing, and rarely, hopping and skipping. Repetitive odd movements of the fingers or hands, as well as imitating the speech or movements of others also may indicate that catatonia is present. There are no laboratory or other tests that can be used to positively diagnose this condition, but medical and neurological tests are necessary to rule out underlying lesions or disorders that may be causing the symptoms observed.

Treatment

Treatment of catatonia includes medications such as benzodiazipines (which are the preferred treatment) and rarely **barbiturates**. Antipsychotic drugs may be appropriate in some cases, but often cause catatonia to worsen. **Electroconvulsive therapy** may prove beneficial for clients who do not respond to medication. If these approaches are unsuccessful, treatment will be redirected to attempts to control the signs and symptoms of the illness.

Prognosis

Catatonia usually responds quickly to medication interventions.

WWW.BOOKBAZ.IR

KEY TERMS

Barbiturates—A group of medicines that slow breathing and lower the body temperature and blood pressure. They can be habit forming and are now used chiefly for anesthesia.

Benzodiazipines—This group of medicines is used to help reduce anxiety (especially before surgery) and to help people sleep.

Electroconvulsive therapy—This type of therapy is used to treat major depression and severe mental illness that does not respond to medications. A measured dose of electricity is introduced into the brain in order to produce a convulsion. Electroconvulsive therapy is safe and effective.

Mutism—The inability or refusal to speak.

Negativism—Behavior characterized by resistance, opposition, and refusal to cooperate with requests, even the most reasonable ones.

Neuroleptic drugs—Antipsychotic drugs, including major tranquilizers, used in the treatment of psychoses like schizophrenia.

Prevention

There is currently no known way to prevent catatonia because the cause has not yet been identified. Research efforts continue to explore possible origins. Avoiding excessive use of neuroleptic drugs can help minimize the risk of developing catatonic-like symptoms.

Catecholamines tests

Definition

Catecholamines is a collective term for the hormones epinephrine, norepinephrine, and dopamine. Manufactured chiefly by the chromaffin cells of the adrenal glands, these hormones are involved in readying the body for the "fight-or-flight" response (also known as the alarm reaction). When these hormones are released, the heart beats stronger and faster, blood pressure rises, more blood flows to the brain and muscles, the liver releases stores of energy as a sugar the body can readily use (glucose), the rate of breathing increases and airways widen, and digestive activity slows. These reactions direct more oxygen and fuel to the organs most active in responding to stress—mainly the brain, heart, and skeletal muscles.

Purpose

Pheochromocytoma (a tumor of the chromaffin cells of the adrenal gland) and tumors of the nervous system (neuroblastomas, ganglioneuroblastomas, and ganglioneuromas) that affect hormone production can cause excessive levels of different catecholamines to be secreted. This results in constant or intermittent high blood pressure (**hypertension**). Episodes of high blood pressure may be accompanied by symptoms such as **headache**, sweating, **palpitations**, and **anxiety**. The catecholamines test can be ordered, then, to determine if high blood pressure and other symptoms are related to improper hormone secretion and to identify the type of tumor causing elevated catecholamine levels.

Description

The catecholamines test can be performed on either blood or urine. If performed on blood, the test may require one or two samples, depending on the physician's request. The first blood sample will be drawn after the patient has been lying down in a warm, comfortable environment for at least 30 minutes. If a second sample is needed, the patient will be asked to stand for 10 minutes before the blood is drawn. Instead of a venipuncture, which can be stressful for the patient, possibly increasing catecholamine levels in the blood, a plastic or rubber tube-like device called a catheter may be used to collect the blood samples. The catheter would be inserted in a vein 24 hours in advance, eliminating the need for needle punctures at the time of the test.

It may take up to a week for a lab to complete testing of the samples. Because blood levels of catecholamines commonly go up and down in response to

KEY TERMS

Dopamine—Dopamine is a precursor of epinephrine and norepinephrine.

Epinephrine—Epinephrine, also called adrenaline, is a naturally occurring hormone released by the adrenal glands in response to signals from the sympathetic nervous system. These signals are triggered by stress, exercise, or by emotions such as fear.

Ganglioneuroma—A ganglioneuroma is a tumor composed of mature nerve cells.

Neuroblastoma—Neuroblastoma is a tumor of the adrenal glands or sympathetic nervous system. Neuroblastomas can range from being relatively harmless to highly malignant.

Norepinephrine—Norepinephrine is a hormone secreted by certain nerve endings of the sympathetic nervous system, and by the medulla (center) of the adrenal glands. Its primary function is to help maintain a constant blood pressure by stimulating certain blood vessels to constrict when the blood pressure falls below normal.

Pheochromocytoma—A pheochromocytoma is a tumor that originates from the adrenal gland's chromaffin cells, causing overproduction of catecholamines, powerful hormones that induce high blood pressure and other symptoms.

such factors as temperature, **stress**, postural change, diet, **smoking**, **obesity**, and many drugs, abnormally high blood test results should be confirmed with a 24-hour urine test. In addition, catecholamine secretion from a tumor may not be steady, but may occur periodically during the day, and potentially could be missed when blood testing is used. The urine test provides the laboratory with a specimen that reflects catecholamine production over an entire 24-hour period. If urine is tested, the patient or a healthcare worker must collect all the urine passed over the 24-hour period.

Preparation

It is important that the patient refrain from using certain medications, especially cold or allergy remedies, for two weeks before the test. Certain foods—including bananas, avocados, cheese, coffee, tea, cocoa, beer, licorice, citrus fruit, vanilla, and Chianti—must be avoided for 48 hours prior to testing. However, people should be sure to get adequate amounts of vitamin C before the test, because this vitamin is necessary for catecholamine formation. The patient should be **fasting** (nothing to eat or drink) for 10 to 24 hours before the blood test and should not smoke for 24 hours beforehand. Some laboratories may call for additional restrictions. As much as possible, the patient should try to avoid excessive physical **exercise** and emotional stress before the test, because either may alter test results by causing increased secretion of epinephrine and norepinephrine.

Patients collecting their own 24-hour urine samples will be given a container with special instructions. The urine samples must be refrigerated.

Results

Reference ranges are laboratory-specific, vary according to methodology of testing, and differ between blood and urine samples. If testing is done by the method called High Performance Liquid Chromatography (HPLC), typical values for blood and urine follow.

Risks

Risks for the blood test are minimal, but may include slight bleeding from the venipuncture site, **fainting** or feeling lightheaded after blood is drawn, or blood accumulating under the puncture site (hematoma). There are no risks for the urine test.

Reference ranges for blood catecholamines

Supine (lying down): Epinephrine less than 50 pg/mL, norepinephrine less than 410 pg/mL, and dopamine less than 90 pg/mL. Standing: Values for blood specimens taken when the subject is standing are higher than the ranges for supine posture for norepinephrine and epinephrine, but not for dopamine.

Reference ranges for urine catecholamines

Epinephrine 0–20 micrograms per 24 hours; norepinephrine 15–80 micrograms per 24 hours; dopamine 65–400 micrograms per 24 hours.

Abnormal

Depending on the results, high catecholamine levels can indicate different conditions and/or causes:

WWW.BOOKBAZ.IR

- High catecholamine levels can help to verify pheochromocytoma, neuroblastoma, or ganglioneuroma. An aid to diagnosis is the fact that an adrenal medullary tumor (pheochromocytoma) secretes epinephrine, whereas ganglioneuroma and neuroblastoma secrete norepinephrine.
- Elevations are possible with, but do not directly confirm, thyroid disorders, low blood sugar (hypoglycemia), or heart disease.
- Electroshock therapy, or shock resulting from hemorrhage or exposure to toxins, can raise catecholamine levels.
- In the patient with normal or low baseline catecholamine levels, failure to show an increase in the sample taken after standing suggests an autonomic nervous system dysfunction (the division of the nervous system responsible for the automatic or unconscious regulation of internal body functioning).

Catheter ablation

Definition

Catheter ablation of an irregular heartbeat involves having a tube (a catheter) inserted into the heart through which electrical energy is sent to either reset the heartbeat or stop the heart from beating so a mechanical pacemaker can be put in place.

Purpose

Irregular heartbeats can occur in healthy people without causing any dangerous symptoms or requiring medical attention. Slight changes in the normal patterns of heartbeats often reset themselves without notice.

But when the heartbeat is greatly disrupted—either because of traumatic injury, disease, **hypertension**, surgery, or reduced blood flow to the heart caused by blockages in the blood vessels that nourish the heart—the condition must be recognized and treated immediately. Otherwise, it can be fatal.

Various drugs can be used to control and help reset these abnormal heart rhythms (**arrhythmias**). The technique of catheter ablation (meaning tube-guided removal) is used to interrupt the abnormal contractions in the heart, allowing normal heart beating to resume. **Atrial fibrillation and flutter** and **Wolff-Parkinson-White syndrome** are two of the most common disorders treated with catheter ablation.

Precautions

The improper correction of abnormal heartbeats can cause additional arrhythmias and can be fatal. Abnormalities in different areas of the heart cause different types of irregular heartbeats; the type of arrhythmia must be clearly defined before this procedure can be properly done.

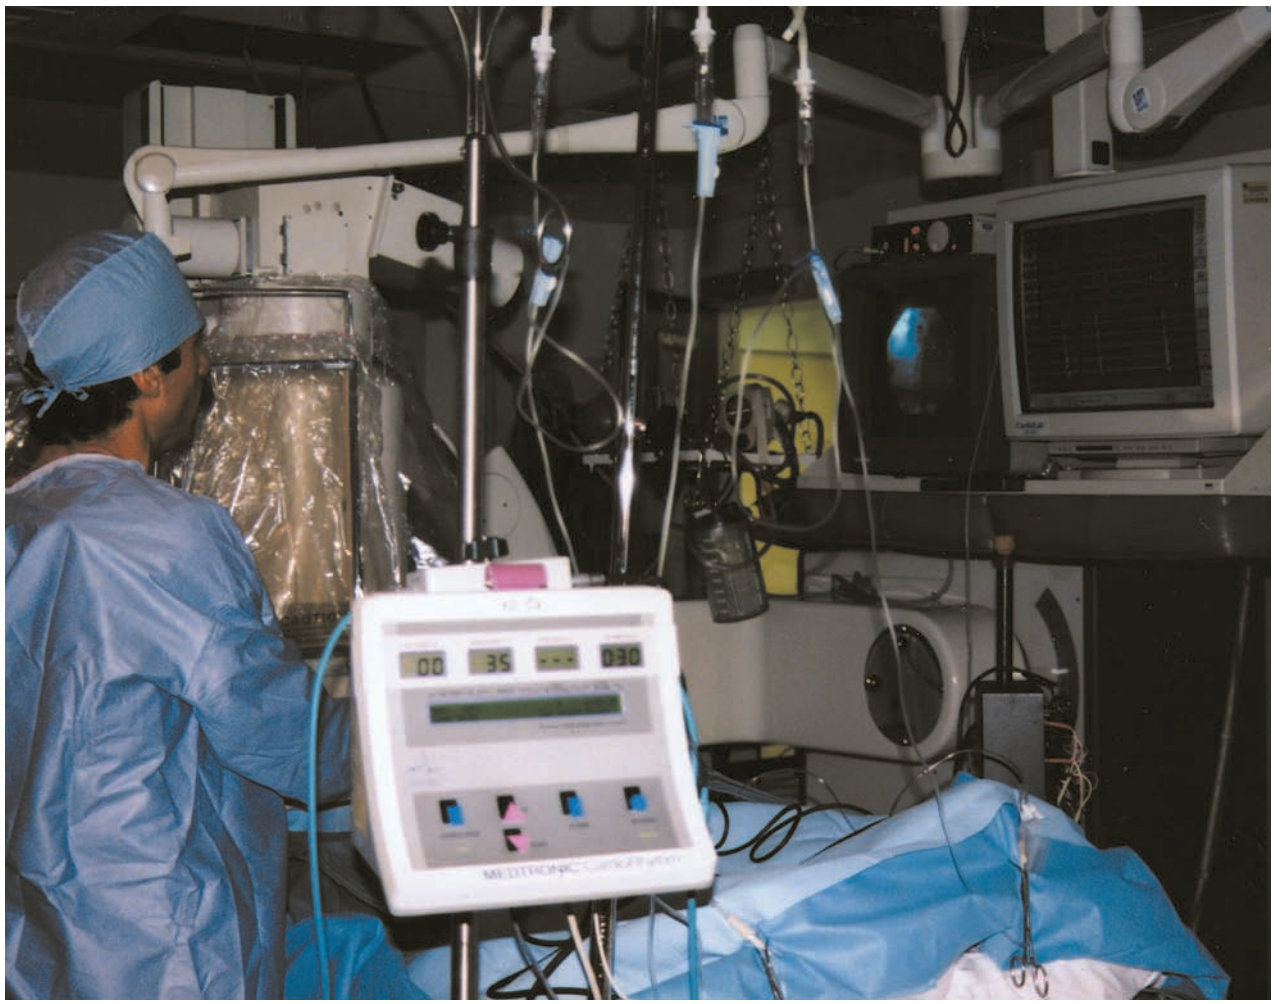
Description

Catheter ablation involves delivering highly focused heat (or radio frequency energy) to specific areas of the heart. Radio frequency energy is very rapidly alternating electrical current that is produced at the tip of the catheter that is placed inside the heart. At the same time as the catheter is inserted, a second electrode is placed on the patient's skin. When the catheter is energized, the body conducts the energy from the catheter's tip, through the heart and to the electrode on the skin's surface, completing the circuit.

Although very little electricity is given off by the catheter, the instrument does generate a large amount of heat. This heat is absorbed by the heart tissue, causing a small localized burn and destroying the tissue in contact with the catheter tip; in this way, small regions of heart tissue are burned in a controlled manner. This controlled destruction of small sections of heart muscle actually kills the nerve cells causing the irregular heartbeat, stopping the nerve signals that are passing through this section of the heart. This usually causes the irregular heartbeat to be reset into a normal heartbeat.

Preparation

People can undergo this procedure by having general **anesthesia** or by taking medicines to make them relaxed and sleepy (sedatives) along with painkillers. Once the type of irregular heartbeat is identified and these medicines are given, the catheter is inserted through a blood vessel and into the heart.



During catheter ablation, a long flexible tube called a catheter is inserted into a vein in the patient's groin and guided toward the heart. A special x-ray machine called a fluoroscope helps the electrophysiologist visualize correct placement. *(Collette Placek.)*

Importantly, correct placement of the catheter is visualized by using a specialized type of x-ray machine called a fluoroscope.

Aftercare

Being sure the patient is comfortable during and after this procedure is very important. However, because each person may have a different arrhythmia and possibly other medical problems as well, each patient's needs must be evaluated individually.

Results

Depending upon the type of irregular heartbeat being treated, either the normal heartbeat resumes after treatment or the ability of the heart to beat on its own is lost, requiring the insertion of a pacemaker to stimulate the heart to beat regularly.

Risks

Overall, fewer than 5% of people having this procedure experience complications. The most common complications are usually related to blood vessel injury when the catheter is inserted and to different heart-related problems due to the moving of the catheter within the heart. However, in general, this technique is safe and can control many different heart arrhythmias.

Abnormal

Additional irregular heartbeats can occur as a result of this procedure, as can damage to the blood

WWW.BOOKBAZ.IR

KEY TERMS

Fluoroscope—A specialized x-ray machine used to visualize the placement of the catheter when attempting to correct irregular heartbeats.

Pacemaker—An electrical device that has electrodes attached to the heart to electrically stimulate the heart to beat normally. Pacemakers can be internal (placed under the skin) or external, with the electrodes placed on the skin or threaded through a tube placed into the heart.

vessels that feed the heart. Because this procedure requires the use of the x-ray machine called a fluoroscope, there is exposure to x-ray radiation, but it is doubtful that this is harmful in adult patients. The risk versus benefit is considered with pediatric patients.

Cat cry syndrome *see* **Cri du chat syndrome**

Cat-scratch disease

Definition

Cat-scratch disease is an uncommon infection that typically results from a cat's scratch or bite. Most sufferers experience only moderate discomfort and find that their symptoms clear up without any lasting harm after a few weeks or months. Professional medical treatment is rarely needed.

Description

Cat-scratch disease (also called cat-scratch fever) is caused by the *Bartonella henselae* bacterium, which is found in cats around the world and is transmitted from cat to cat by fleas. Researchers have discovered that large numbers of North American cats carry antibodies for the disease (meaning that the cats have been infected at some point in their lives). Some parts of North America have much higher rates of cat infection than others, however. *Bartonella henselae* is uncommon or absent in cold climates, which fleas have difficulty tolerating, but prevalent in warm, humid places such as Memphis, Tennessee, where antibodies were found in 71% of the cats tested. The bacterium, which remains in a cat's bloodstream for several months after infection, seems to be harmless to most cats, and normally an infected cat will not display any symptoms. Kittens (cats less than one year old) are more likely than adult cats to be carrying the infection.

Bartonella henselae can infect people who are scratched or (more rarely) bitten or licked by a cat. It cannot be passed from person to person. Although cats are popular pets found in about 30% of American households, human infection appears to be rare. One study estimated that for every 100,000 Americans there are only 2.5 cases of cat-scratch disease each year (2.5/100,000). It is also unusual for more than one family member to become ill; a Florida investigation discovered multiple cases in only 3.5% of the families studied. Children and teenagers appear to be the most likely victims of cat-scratch disease, although the possibility exists that the disease may be more common among adults than previously thought.

Causes and symptoms

The first sign of cat-scratch disease may be a small blister at the site of a scratch or bite three to 10 days after injury. The blister (which sometimes contains pus) often looks like an insect bite and is usually found on the hands, arms, or head. Within two weeks of the blister's appearance, lymph nodes near the site of injury become swollen. Often the infected person develops a fever or experiences **fatigue** or headaches. The symptoms usually disappear within a month, although the lymph nodes may remain swollen for several months. Hepatitis, **pneumonia**, and other dangerous complications can arise, but the likelihood of cat-scratch disease posing a serious threat to health is very small. **AIDS** patients and other immunocompromised people face the greatest risk of dangerous complications.

Occasionally, the symptoms of cat-scratch disease take the form of what is called Parinaud's oculoglandular syndrome. In such cases, a small sore develops on the palpebral conjunctiva (the membrane lining the inner eyelid), and is often

KEY TERMS

Acetaminophen—A drug for relieving pain and fever.

AIDS—Acquired immunodeficiency syndrome. A disease that attacks the immune system.

Antibiotics—A category of manufactured substances used to combat infection.

Antibodies—Special substances created by the body to combat infection.

Bacterium—A tiny organism. Some bacteria cause disease.

Hepatitis—A disease that inflames the liver.

Immune system—A body system that combats disease.

Immunocompromised—Having a damaged immune system.

Lymph nodes—Small, kidney-shaped organs that filter a fluid called lymph.

Pneumonia—A disease that inflames the lungs.

Pus—A thick yellowish or greenish fluid.

accompanied by **conjunctivitis** (inflammation of the membrane) and swollen lymph nodes in front of the ear. Researchers suspect that the first step in the development of Parinaud's oculoglandular syndrome occurs when *Bartonella henselae* bacteria pass from a cat's saliva to its fur during grooming. Rubbing one's eyes after handling the cat then transmits the bacteria to the conjunctiva.

Diagnosis

A family doctor should be called whenever a cat scratch or bite fails to heal normally or is followed by a persistent fever or other unusual symptoms such as long-lasting bone or joint **pain**. The appearance of painful and swollen lymph nodes is another reason for consulting a doctor. When cat-scratch disease is suspected, the doctor will ask about a history of exposure to cats and look for evidence of a cat scratch or bite and swollen lymph nodes. A blood test for *Bartonella henselae* may be ordered to confirm the doctor's diagnosis.

Treatment

For otherwise healthy people, rest and over-the-counter medications for reducing fever and discomfort (such as **acetaminophen**) while waiting for the disease to run its course are usually all that is necessary. **Antibiotics** are prescribed in some cases, particularly when complications occur or the lymph nodes remain swollen and painful for more than two or three months, but there is no agreement among doctors about when and how they should be used. If a lymph node becomes very swollen and painful, the family doctor may decide to drain it.

Prognosis

Most people recover completely from a bout of cat-scratch disease. Further attacks are rare.

Prevention

Certain common–sense precautions can be taken to guard against the disease. Scratches and bites should be washed immediately with soap and water, and it is never a good idea to rub one's eyes after handling a cat without first washing one's hands. Children should be told not to play with stray cats or make cats angry. Immunocompromised people should avoid owning kittens, which are more likely than adult cats to be infectious. Because cat-scratch disease is usually not a life-threatening illness and people tend to form strong emotional bonds with their cats, doctors do not recommend getting rid of a cat suspected of carrying the disease.

Celiac disease

Definition

Celiac disease—also known as sprue, celiac sprue, non-tropical sprue, and gluten-sensitive enteropathy—is a lifelong autoimmune disease in which the body's reaction to gluten causes damage to the intestines that results in poor absorption of nutrients.

Description

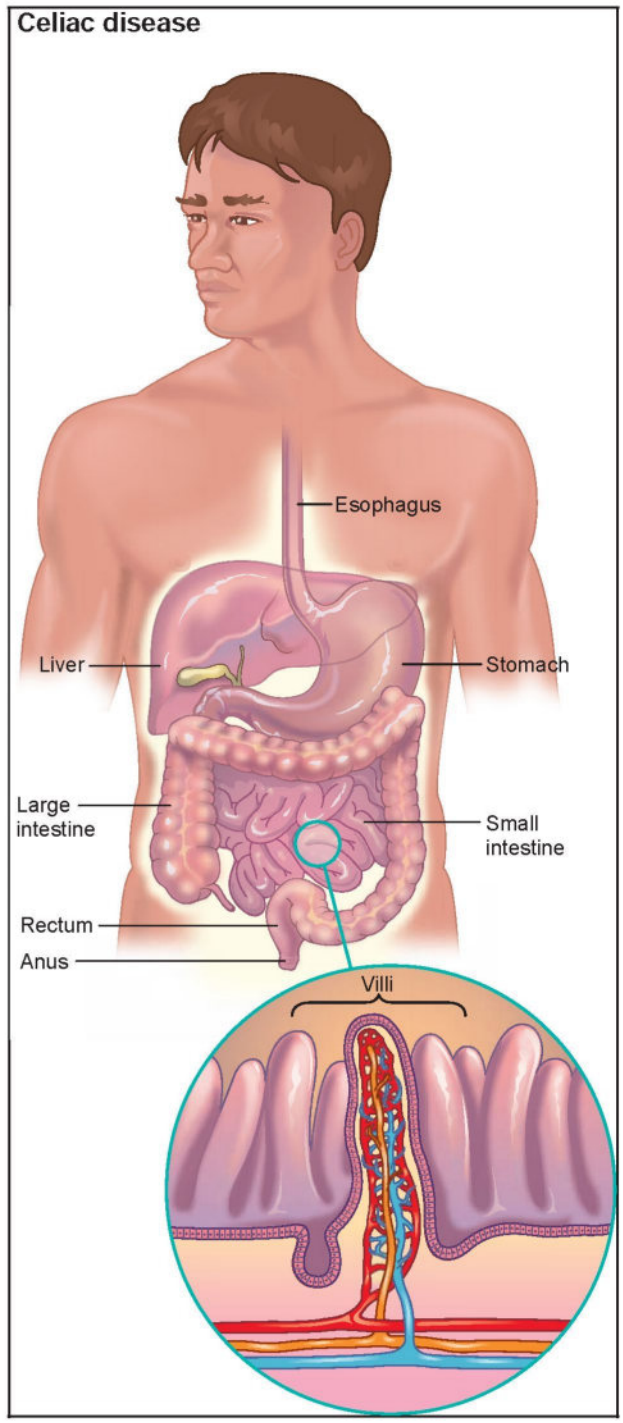
Absorption of most nutrients occurs in the small intestine. The intestine is lined with microscopic, hair-like projections called villi, and it is through these villi that nutrients are absorbed. Villi project into the intestine and provide an increased surface area for absorption. Damage to the villi results in inadequate absorption, especially of **vitamins**, **minerals**, and fats.

Celiac disease is an autoimmune disease. Whenever immune system cells in the body sense the presence of foreign material, they produce proteins called antibodies that act to disable the foreign material. In an autoimmune disease, the body treats some of its own cells as foreign and attacks them. Celiac disease is also classified as a malabsorption disease because the cells that are damaged by the body's immune system are cells of the villi lining the small intestine. When these cells are damaged, the villi flatten out, decreasing the surface area available for absorption. Nutrients are not properly absorbed, and vitamin and mineral deficiencies often develop.

The symptoms of celiac disease were described as early as 1888, but it was not until the 1950s that physicians began to understand what caused the disease. Dutch pediatrician W. K. Dicke was the first person to make the connection between the consumption of foods containing wheat and symptoms of celiac disease. Today, researchers know that the problem substance is gluten, a protein found in wheat, rye, barley, and products made from these grains such as flour, bread, and pasta. The role of oats and oat products in celiac disease remains controversial.

Demographics

Celiac disease is most common among people of Northern European ancestry and is uncommon to rare among people of African or Asian ancestry. Initially, celiac disease was thought to be uncommon in the United States, but improvements in **genetic testing** and disease awareness have changed that picture. Experts believe that in areas of the world settled primarily by Europeans, including the United States,



When people with celiac disease eat foods or use products containing gluten, their immune system responds by damaging or destroying villi in the intestine. Villi allows nutrients from food to be absorbed into the bloodstream; without healthy villi, a person becomes malnourished, regardless of the quantity of food eaten. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

about 1 in every 133 people has celiac disease; prevalence for non-Hispanic whites in the United States is thought to be closer to 1 in 100 (1%). The disease has an inherited component, and the rate increases to 1 of every 22 people who are blood relatives of a parent, sibling, or child with the disease. In about 70% of identical twins, if one has celiac disease, the other also has it. Celiac disease is also more common among people with other genetically related autoimmune diseases, such as **systemic lupus erythematosus**, type 1 diabetes (juvenile diabetes), **rheumatoid arthritis**, and autoimmune thyroid disease.

People of any age can be diagnosed with celiac disease. However, there are two common peaks for diagnosis, one between 8–15 months (which is shortly after infants usually begin eating wheat products) and another between 30–40 years in adults.

Causes and symptoms

Researchers have traced the genetic component of celiac disease to a cluster of genes on chromosome six. Multiple genes are involved, which may account for the variation in symptoms and inheritability of the disease. Often, symptoms of the disease develop after a serious infection, physical **trauma**, **pregnancy**, or surgery. Researchers do not know why **stress** on the body appears to trigger symptoms.

Symptoms of celiac disease are varied. Some people have the disease (as diagnosed by samples that show damage to the small intestine), but they show no symptoms. Others go along for years with annoying or intermittent symptoms, and some, especially children, show severe symptoms of **malnutrition** that stunt growth despite eating a healthy diet. Symptoms are similar to those of other, more common, digestive diseases. Often, celiac disease is initially misdiagnosed.

Common symptoms of celiac disease fall into two categories, those primarily related to the immediate problems of digesting food and those that result mainly from long-term deficiencies in vitamins and minerals. Symptoms primarily related to immediate difficulties in digestion include:

- chronic diarrhea
- foul-smelling grayish stools, resulting from the inability to properly digest fats
- gas, abdominal bloating
- abdominal cramps
- weight loss
- among children, symptoms including dental enamel defects

Other symptoms that develop because of vitamin and mineral deficiencies can include:

- iron deficiency anemia (low red blood cell count)
- joint pain, muscle pain, muscle cramps
- osteoporosis (inadequate calcium absorption)
- tingling in the legs from nerve damage
- seizures
- bleeding disorders (inadequate vitamin K)
- missed menstrual periods
- infertility (in women), frequent miscarriages
- failure to thrive in infants
- delayed mental and physical growth in children

Other symptoms include:

- fatigue
- irritability and behavioral changes, especially in children
- pale sores inside the mouth
- dermatitis herpetiformis (an itchy skin rash that usually appears on the trunk, buttocks, neck, and scalp)

Diagnosis

Celiac disease can be difficult to diagnose because its symptoms are similar to those of so many other diseases. Often, it is initially misdiagnosed as **irritable bowel syndrome** or Crohn's disease. Stool examination, blood tests, and lactose (milk sugar) tolerance tests are often done when the patient first complains of symptoms, but there are two definitive tests for celiac disease.

The immune system of people with celiac disease produces higher than normal levels of certain antibodies. Blood tests can detect abnormal levels of these antibodies. If blood tests are positive, a small bowel **endoscopy** with biopsies is done. Endoscopies are usually performed in a doctor's office or an outpatient clinic while the patient is under light **sedation**. In this procedure, the physician inserts a tube, called an endoscope, down the patient's throat, through the patient's stomach, and into the upper part of the small intestine. A tiny camera at the end of the endoscope allows the doctor to see if there is damage to villi. During this procedure, the doctor also removes small tissue samples (biopsies) from the intestinal lining in order to look for cell damage under the microscope. Presence of a specific type of damage is a positive diagnosis for celiac disease.

WWW.BOOKBAZ.IR

Treatment

There is no cure for celiac disease. The only treatment is life-long avoidance of any foods that contain gluten. This means not eating foods that contain wheat, rye, and barley, such as bread or baked goods, pizza, spaghetti, and many processed foods that use flour as a thickening agent. Often oats need to be avoided, particularly by children, due to risk of cross contamination.

When individuals fail to improve on a **gluten-free diet**, it is sometimes because they are unintentionally consuming sources of hidden gluten. A few people on truly gluten-free **diets** do not improve. They can be treated with corticosteroid drugs to reduce inflammation, but this does not heal the intestine.

Nutrition and dietary concerns

Individuals newly diagnosed with celiac disease may find it helpful to meet with a nutritionist or dietitian to aid with meal planning. Two issues need to be addressed. First, determining what is safe to eat, and second, learning how to get the right balance of nutrients in a gluten-free diet. Complicating matters, damage to the intestines may make some people lactose intolerant, so that they either cannot eat or must limit dairy products in their diet.

Many cookbooks are available to help people on a gluten-free diet. Home cooks must learn to substitute ingredients, such as cornstarch and rice flour, for wheat flour in their foods. An increasing number of gluten-free foods are available commercially. However, these often cost more than their gluten-containing counterparts. Foods people with celiac disease can safely eat include:

- plain fruits and vegetables
- plain meat that has not been breaded, coated, or mixed with fillers
- potatoes
- rice (all types)
- cornmeal, cornstarch, and products made of corn, such as corn tortillas
- tapioca
- buckwheat
- dried beans and peas
- nuts
- quinoa
- amaranth
- arrowroot

Other foods must be avoided. Individuals with celiac disease must also avoid cross-contamination with these foods. For example, they should not cut gluten-free bread using a knife that has cut regular wheat bread unless the knife has been thoroughly washed. Even small amounts of gluten can cause damage to the intestine. Some of the foods people with celiac disease must avoid are:

- wheat flours, including durum flour, enriched flour, graham flour, semolina flour, and white flour
- wheat germ, wheat starch, wheat bran, cracked wheat
- products made with the above mentioned wheat products such as pasta, bread, cakes, cookies
- barley, barley flour, and products made with barley
- rye, rye flour, and products made with rye
- triticale and other wheat hybrids
- oats

Learning how to read food labels is very important to people who must avoid gluten. However, this may become easier in time. In January 2007, the United States Food and Drug Administration (FDA) published preliminary regulations for foods that could be labeled "gluten free." As of August 2014, all manufacturers had to comply with the FDA mandated gluten-free labeling rules. Nonetheless, people with celiac disease must be alert to so-called hidden sources of gluten that often serve as binders or thickeners in commercially prepared foods. Some of these subtle sources of gluten are listed below.

- starch (type unspecified)
- modified food starch
- hydrolyzed vegetable protein (HVP)
- hydrolyzed plant protein (HPP)
- texturized vegetable protein (TVP)
- binders
- fillers
- extenders
- excipients (ingredients used in medications that do not have medicinal value, such as coatings of tablets. Consult a pharmacist or physician before taking drugs, vitamins, etc.)
- malt

Some brands of commercially prepared French fries, potato chips, hot dogs, meatballs, gravy mixes, soups, soy sauce, and candy contain these hidden sources of gluten. Others are gluten-free. A nutritionist and dietitian can help people with celiac disease learn to read labels accurately to distinguish that foods are safe for them.

KEY TERMS

Antibodies—Proteins that provoke the immune system to attack particular substances. In celiac disease, the immune system makes antibodies to a component of gluten.

Gluten—A protein found in wheat, rye, barley, and oats.

Villi—Tiny, finger-like projections that enable the small intestine to absorb nutrients from food.

Therapy

Switching to a gluten-free diet requires major lifestyle changes. It can be especially hard on children and teens who want to be able to go out with their friends and eat pizza and fast food. Many people find Internet support groups are helpful in making the transition to a gluten-free diet.

Prognosis

The intestines of people with celiac disease who go on a gluten-free diet heal. In children, the healing usually takes three to six months. In adults, healing can take two years. The intestinal villi remain intact and function properly so long as the diet remains free of gluten, but the disease is never cured.

People who are not diagnosed or who do not stay on a gluten-free diet face increased chances of developing cancer of the intestine. They may also develop **osteoporosis** because of poor **calcium** absorption. Other vitamin and mineral deficiencies may contribute to a multitude of health problems. Untreated pregnant women have higher than normal rates of **miscarriage** and babies born with **birth defects**, especially neural tube defects, which arise from inadequate amounts of **folic acid**. Untreated children may have stunted mental and physical growth.

Prevention

Celiac disease is a genetic autoimmune disorder that cannot be prevented. Once diagnosed, the only way to prevent symptoms and complications is to follow a strictly gluten-free diet.

REVISED BY DAVID NEWTON

Cell therapy

Definition

Cell therapy is the transplantation of human or animal cells to replace or repair damaged tissue.

Purpose

The purpose of cell therapy is to introduce cells into the body that will grow and replace damaged

WWW.BOOKBAZ.IR

tissue. Cell therapy differs from conventional stem cell therapy in that the cells injected into the body in cell therapy are already differentiated (e.g., muscle cells, gland cells), whereas conventional stem cell therapy utilizes undifferentiated, usually embryonic cells. Cell therapy has long been used by alternative medicine practitioners who have claimed great benefits; these have not been replicated by conventional medical practitioners.

Description

The theory behind cell therapy has been in existence for several hundred years. The first recorded discussion of the concept of cell therapy can be traced to Phillippus Aureolus Paracelsus (1493–1541), a German-Swiss physician and alchemist who wrote in his *Der grossen Wundartzney* (Great Surgery Book) in 1536 that "the heart heals the heart, lung heals the lung, spleen heals the spleen; like cures like." Paracelsus and many of his contemporaries agreed that the best way to treat an illness was to use living tissue to restore the ailing. In 1667, at a laboratory in the palace of Louis XIV, Jean-Baptiste Denis (1640–1704) attempted to transfuse blood from a calf into a mentally ill patient. Since blood **transfusion** is, in effect, a form of cell therapy, this could be the first documented case of this procedure. However, the first recorded attempt at non-blood cellular therapy occurred in 1912 when German physicians attempted to treat children with **hypothyroidism** (underactive thyroid gland), with thyroid cells.

In 1931, Dr. Paul Niehans (1882–1971), a Swiss physician, became known as "the father of cell therapy" quite by chance. After a surgical accident by a colleague, Niehans attempted to replace a patient's severely damaged parathyroid glands with those of a steer. When the patient began to rapidly deteriorate before the transplant could take place, Niehans decided to dice the steer's parathyroid gland into fine pieces, mix the pieces in a saline solution, and inject them into the dying patient. He reported that immediately the patient began to improve and, in fact, lived for another 30 years.

Cell therapy as alternative medicine

Cell therapy as performed by alternative medicine practitioners is very different from the controlled research done by conventional stem cell medical researchers. Alternative practitioners refer to their form of cell therapy by several other different names including xenotransplant therapy, glandular therapy, and fresh cell therapy. The procedure involves the injection of either whole fetal xenogenic (animal) cells (e.g., from sheep, cows, pigs, and sharks) or cell extracts from human tissue. Several different types of cells may be administered simultaneously.

Just as Paracelsus's theory of "like cures like," the types of cells that are administered correspond in some way with the organ or tissue in the patient that is failing. In other words, the cells are not species specific, but only organ specific. Alternative practitioners cannot explain how this type of cell therapy works, but proponents claim that the injected cells travel to the similar organ from which they were taken to revitalize and stimulate that organ's function and regenerate its cellular structure. Supporters of cellular treatment believe that embryonic and fetal animal tissue contain active therapeutic agents distinct from **vitamins**, **minerals**, hormones, or enzymes. This theory and these claims are rejected by practitioners of conventional medicine.

Proponents of cell therapy claim that it has been used successfully to rebuild damaged cartilage in joints, repair spinal cord injuries, strengthen a weakened immune system, treat autoimmune diseases such as **AIDS**, and help patients with neurological disorders such as Alzheimer's disease, Parkinson's disease, and **epilepsy**. Further claims of positive results have been made in the treatment of a wide range of chronic conditions such as arteriosclerosis, congenital defects, and **sexual dysfunction**. The therapy has also been used to treat cancer patients at a number of clinics in Tijuana, Mexico. Most of these claims are anecdotal. None of these application is supported by well-designed, controlled clinical studies.

Cell therapy as conventional medicine

Cell therapy in conventional medicine is still in the research and early clinical trial stage. This research is an outgrowth of stem cell research, and is performed in government-regulated laboratories by traditionally trained scientists. Embryonic stem cells are cells taken from an embryo before they have differentiated (specialized) into such specific cell types as muscle cells, nerve cells, or skin cells. In laboratory test tube and animal experiments, stem cells often can be manipulated into differentiating into specific types cells that have the potential to replace differentiated cells in damaged organs. For example, in early 2008, researchers at the Diabetic Research Institute at the University of Miami in Florida were able to convert embryonic stem cells into insulin-producing cells and use them to treat insulin-dependent diabetes in mice.

Stem cells also have been found in bone marrow, and work is underway to see if other cells can be

KEY TERMS

Anaphylactic shock—A severe allergic reaction that causes blood pressure drop, racing heart, swelling of the airway, rash, and possibly convulsions.

Culturing—To grow cells in a special substance, or media, in the laboratory.

Encephalitis—Inflammation of the brain that is often fatal.

Xenotransplant—Transplantation of animal cells or tissues into a human.

manipulated into transforming into differentiated cells. In January 2009, researchers at Northwestern University's Feinberg School of Medicine in Chicago announced that they had used a patient's own bone marrow stem cells to improve early symptoms of **multiple sclerosis**. Researchers noted improvement only in patients with early symptoms; in earlier research those with advanced symptoms had not improved. Other researchers are working on treating symptoms of **muscular dystrophy** with fully differentiated myoblasts (a kind of muscle cell) with mixed results. Still other are working with using cartilage cells (chondrocyte cells) to repair cartilage in joints such as the knee.

Stem cell therapy has potential to treat a wide range of diseases and disorders, but it is, for the most part, still in the test tube and animal research stage of development. Because of the ethical questions raised when the harvesting of stem cells destroys embryos, the United States has placed restrictions on some human stem cell research. These restrictions, however, do not apply to research that does not destroy embryos. However, much stem cell research is being carried out in other countries, especially Thailand, South Korea, and China, where fewer restrictions are placed on obtaining human stem cells for experimentation. A list of FDA-approved clinical trials involving stem cell therapy can be found at http://www.clinicaltrials.gov.

Preparation

Alternative practitioners use several processes to prepare cells for use. One procedure involves extracting cells from the patient and then culturing them in a laboratory until they multiply to the level needed for transplantation back into the same patient. Another procedure uses freshly removed fetal animal tissue that has been processed and suspended in a saline (salt water) solution. The preparation of fresh cells then may be either injected immediately into the patient or preserved by being freeze-dried or deep-frozen in liquid nitrogen before being injected. Injected cells may or may not be tested for pathogens, such as bacteria, viruses, or parasites, before use. Conventional cell therapy researchers work in laboratories where the growing environment of the cells is highly controlled and monitored to prevent contamination.

Risks

Many forms of cell therapy in the United States are highly experimental procedures. Patients should approach any cell therapy treatments with extreme caution, inquire about their proven efficacy and legal use in the United States or their home country, and should only accept treatment only from a licensed physician who should educate the patient completely on the risks and possible side effects involved with cell therapy. These same cautions apply for patients interested in participating in FDA-approved clinical trials of cell therapy treatments.

Because cell therapy encompasses a wide range of treatments and applications and many of these treatments are unproven and highly experimental, the full range of possible side effects of the treatments is not yet known. Anaphylactic **shock**, immune system reactions, and encephalitis are just a few of the known reported side effects in some patients to date.

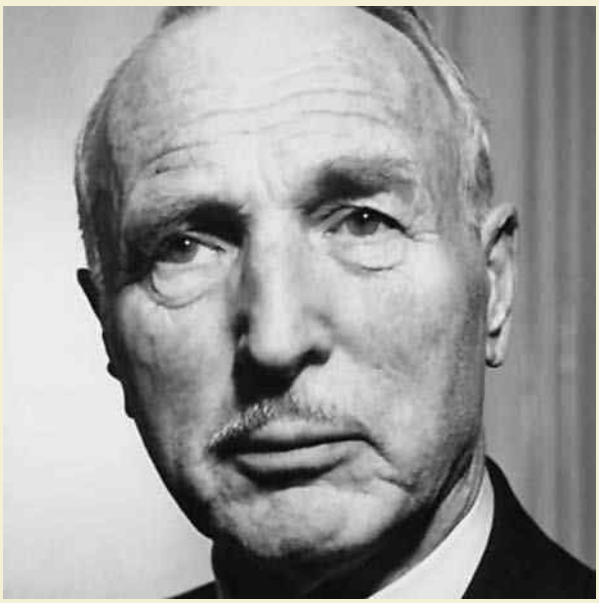
Patients undergoing cell therapy treatments which use cells transplanted from animals or other humans run the risk of cell rejection, in which the body recognizes the cells as a foreign substance and uses immune system cells to attack and destroy them. Some forms of cell therapy use special coatings on the cells in an attempt to trick the immune system into recognizing the new cells as native to the body. There is also the chance of the cell solution transmitting a bacterial, viral, fungal, or parasitic infection to the patient. Careful screening and testing of cells for pathogens can reduce this risk.

Research and general acceptance

Cell therapy as alternative healers practice it is generally rejected as effective by the traditionally-trained scientific community. Most of the claims made for these therapies are based on anecdotal evidence and are not backed by controlled clinical trials. While some mainstream cell therapy procedures have shown some success in clinical studies, others are still largely unproven, including cell therapy for cancer

WWW.BOOKBAZ.IR

PAUL NIEHANS (1882–1971)



(© Bettmann/Corbis.)

Paul Niehans was born and raised in Switzerland. His father, a doctor, was dismayed when he entered the seminary, but Niehans quickly grew dissatisfied with religious life and took up medicine after all. He first studied at Bern, then completed an internship in Zurich.

Niehans enlisted in the Swiss Army in 1912. When war erupted in the Balkans, Niehans set up a hospital in Belgrade, Yugoslavia. The war provided him the opportunity to treat numerous patients, gaining a firsthand knowledge of the body and its workings.

Since 1913, Niehans had been intrigued with Alexis Carrel's experiments concerning the adaptive abilities of cells, though Niehans himself specialized in glandular transplants and by 1925 was one of the leading glandular surgeons in Europe.

Niehans referred to 1931 as the birth year of cellular therapy. That year, he treated a patient suffering from tetany whose parathyroid had been erroneously removed by another physician. Too weak for a glandular transplant, the patient was given injections of the parathyroid glands of steer, and she soon recovered. Niehans made more injections, even experimenting on himself, and reported he could cure illnesses through injections of live cells extracted from healthy animal organs. He believed adding new tissue stimulated rejuvenation and recovery.

Niehans treated Pope Pious XII with his injections and was nominated to the Vatican Academy of Science following the pope's recovery.

Niehans remained a controversial figure throughout his life. As of 2014, the Clinique Paul Niehans in Switzerland, founded by his daughter, continued his work. http://www.paulniehans.ch/clinic.htm

treatment. Until large, controlled human clinical studies are performed on cell therapy procedures, they will remain fringe treatments.

Cellulitis

Definition

Cellulitis is a spreading bacterial infection just below the skin surface. It is most commonly caused by *Streptococcus pyogenes* or *Staphylococcus aureus*.

This person's lower leg is swollen and inflamed due to cellulitis. Cellulitis is a *Streptococcus* bacterial infection of the skin and the tissues beneath it. The face, neck, or legs are common sites of cellulitis. *(Custom Medical Stock Photo, Inc.)*

Description

The word "cellulitis" actually means "inflammation of the cells." Specifically, cellulitis refers to an infection of the tissue just below the skin surface. In humans, the skin and the tissues under the skin are the most common locations for microbial infection. Skin is the first defense against invading bacteria and other microbes. An infection can occur when this normally strong barrier is damaged due to surgery, injury, or a burn. Even something as small as a scratch or an insect bite allows bacteria to enter the skin, which may lead to an infection. Usually, the immune system kills any invading bacteria, but sometimes the bacteria are able to grow and cause an infection.

Once past the skin surface, the warmth, moisture, and nutrients allow bacteria to grow rapidly. Disease-causing bacteria release proteins called enzymes which cause tissue damage. The body's reaction to damage is inflammation which is characterized by **pain**, redness, heat, and swelling. This red, painful region grows bigger as the infection and resulting tissue damage spread. An untreated infection may spread to the lymphatic system (**acute lymphangitis**), the lymph nodes (**lymphadenitis**), the bloodstream (**bacteremia**), or into deeper tissues. Cellulitis most often occurs on the face, neck, and legs.

Orbital cellulitis

A very serious infection, called **orbital cellulitis**, occurs when bacteria enter and infect the tissues surrounding the eye. In 50–70% of all cases of orbital cellulitis, the infection spreads to the eye(s) from the sinuses or the upper respiratory tract (nose and throat). Twenty-five percent of orbital infections occur after surgery on the face. Other sources of orbital infection include a direct infection from an eye injury, from a dental or throat infection, and through the bloodstream.

Infection of the tissues surrounding the eye causes redness, swollen eyelids, severe pain, and causes the eye to bulge out. This serious infection can lead to a temporary loss of vision, blindness, brain abscesses, inflammation of the brain and spinal tissues (**meningitis**), and other complications. Before the discovery of **antibiotics**, orbital cellulitis caused blindness in 20% of patients and death in 17% of patients. Antibiotic treatment has significantly reduced the incidence of blindness and death.

Causes and symptoms

Although other kinds of bacteria can cause cellulitis, it is most often caused by *Streptococcus pyogenes* (the bacteria that causes **strep throat**) and *Staphylococcus aureus*. *Streptococcus pyogenes* is the so-called "flesh-eating bacteria" and, in rare cases, can cause a dangerous, deep skin infection called necrotizing fasciitis. Orbital cellulitis may be caused by bacteria which cannot grow in the presence of oxygen (anaerobic bacteria). In children, *Haemophilus influenzae* type B frequently causes orbital cellulitis following a sinus infection.

Streptococcus pyogenes can be picked up from a person who has strep throat or an infected sore. Other cellulitis-causing bacteria can be acquired from direct contact with infected sores. Persons who are at a higher risk for cellulitis are those who have a severe underlying disease (such as cancer, diabetes, and **kidney disease**), are taking steroid medications, have a reduced immune system (because of **AIDS**, organ transplant, etc.), have been burned, have insect bites, have reduced blood circulation to limbs, or have had a leg vein removed for coronary bypass surgery. In addition, chicken pox, human or animal bite **wounds**, skin wounds, and recent surgery can put a person at a higher risk for cellulitis.

The characteristic symptoms of cellulitis are redness, warmth, pain, and swelling. The infected area appears as a red patch that gets larger rapidly within the first 24 hours. A thick red line which progresses toward the heart may appear indicating an infection of the lymph vessels (lymphangitis). Other symptoms which may occur include **fever**, chills, tiredness, muscle aches, and a general ill feeling. Some people also experience nausea, **vomiting**, stiff joints, and hair loss at the infection site.

WWW.BOOKBAZ.IR

The characteristic symptoms of orbital cellulitis are eye pain, redness, swelling, warmth, and tenderness. The eye may bulge out and it may be difficult or impossible to move. Temporary loss of vision, pus drainage from the eye, chills, fever, headaches, vomiting, and a general ill feeling may occur.

Diagnosis

Cellulitis may be diagnosed and treated by a family doctor, an **infectious disease** specialist, a doctor who specializes in skin diseases (dermatologist), or in the case of orbital cellulitis, an eye doctor (ophthalmologist). The diagnosis of cellulitis is based mainly on the patient's symptoms. The patient's recent medical history is also used in the diagnosis.

Laboratory tests may be done to determine which kind of bacteria is causing the infection but these tests are not always successful. If the skin injury is visible, a sterile cotton swab is used to pick up a sample from the wound. If there is no obvious skin injury, a needle may be used to inject a small amount of sterile salt solution into the infected skin, and then the solution is withdrawn. The salt solution should pick up some of the bacteria causing the infection. A blood sample may be taken from the patient's arm to see if bacteria have entered the bloodstream. Also, a blood test may be done to count the number of white blood cells in the blood. High numbers of white blood cells suggest that the body is trying to fight a bacterial infection.

For orbital cellulitis, the doctor may often perform a special x-ray scan called computed tomography scan (CT). This scan enables the doctor to see the patient's head in cross-section to determine exactly where the infection is and see if any damage has occurred. A CT scan takes about 20 minutes.

Treatment

Antibiotic treatment is the only way to battle this potentially life-threatening infection. Mild to moderate cellulitis can be treated with the following antibiotics taken every four to eight hours by mouth:

- penicillins (Bicillin, Wycillin, Pen Vee, V-Cillin)
- erythromycin (E-Mycin, Ery-Tab)
- cephalexin (Biocef, Keflex)
- cloxacillin (Tegopen)

Other medications may be recommended, such as **acetaminophen** (Tylenol) or ibuprofen (Motrin, Advil) to relieve pain, and **aspirin** to decrease fever.

A normally healthy person is usually not hospitalized for mild or moderate cellulitis. General treatment measures include elevation of the infected area, rest, and application of warm, moist compresses to the infected area. The doctor will want to see the patient again to make sure that the antibiotic treatment is effective in stopping the infection.

KEY TERMS

Inflammation—A local, protective response to tissue injury. It is characterized by redness, warmth, swelling, and pain.

Necrotizing fasciitis—A destructive infection which follows severe cellulitis and involves the deep skin and underlying tissues.

Sinuses—Air cavities found in the bones of the head. The sinuses which are connected to the nose are prone to infection.

Persons at high risk for severe cellulitis will probably be hospitalized for treatment and monitoring. Antibiotics may be given intravenously to patients with severe cellulitis. Complications such as deep infection, or bone or joint infections, might require surgical drainage and a longer course of antibiotic treatment. Extensive tissue destruction may require **plastic surgery** to repair. In cases of orbital cellulitis caused by a sinus infection, surgery may be required to drain the sinuses.

Prognosis

Over 90% of all cellulitis cases are cured after seven to ten days of antibiotic treatment. Persons with serious disease and/or those who are taking immunosuppressive drugs may experience a more severe form of cellulitis which can be life threatening. Serious complications include blood **poisoning** (bacteria growing in the blood stream), meningitis (brain and spinal cord infection), tissue death (**necrosis**), and/or lymphangitis (infection of the lymph vessels). Severe cellulitis caused by *Streptococcus pyogenes* can lead to destructive and life-threatening necrotizing fasciitis.

Prevention

Cellulitis may be prevented by wearing appropriate protective equipment during work and sports to avoid skin injury, cleaning cuts and skin injuries with antiseptic soap, keeping wounds clean and protected, watching wounds for signs of infection, taking the entire prescribed dose of antibiotic, and maintaining good general health. Persons with diabetes should try to maintain good blood sugar control.

Central nervous system depressants

Definition

Central nervous system (CNS) depressants are drugs that reduce brain activity.

Purpose

These drugs are used to treat **anxiety**, muscle tension, **pain**, **insomnia**, acute **stress** reactions, panic attacks, and seizure disorders. In higher doses, some of them produce **coma** and **anesthesia**.

Description

Throughout history, humans have sought relief from anxiety and insomnia by using substances that induce a drowsy or calming effect. CNS depressants include a wide range of drugs such as alcohol, the most widely used depressant, **narcotics**, **barbiturates** (Amytal, Nembutal, Seconal), **benzodiazepines** (Ativan, Halcion, Librium, Valium, Xanax), chloral hydrate, Buspirone (Buspar), and Zolpidem (Ambien). Street names for illegal CNS depressants include Reds, Yellows, Blues, Barbs, and Downers.

Precautions

- Most CNS depressants have the potential to be physically and psychologically addictive.
- The body tends to develop tolerance for CNS depressants, and larger doses are needed to achieve the same effects.
- Sudden withdrawal from some CNS depressants can produce rebound insomnia or anxiety, occasionally resulting in life-threatening seizures.
- When depressant medications is discontinued, it should be done gradually to give the body time to adjust.
- The difference is small between effective doses and overdoses for some CNS depressants, such as barbiturates.
- Elderly people are subject to more profound and prolonged effects from CNS depressants.

Side effects

Adverse effects include confusion, **dizziness**, slurred speech, loss of muscle coordination, and impaired thinking and judgment.

Interactions

Interactions with benzodiazepines (Xanax, Ativan, Valium) include:

- These drugs can increase the effects of narcotics and other pain management medications.
- Antifungal drugs, Diflucan, Nizoral, Sporanox, greatly increase and prolong the effects of benzodiazepines.
- Anti-seizure medications, like Tegretol, can decrease the effectiveness of benzodiazepines.
- Cimetidine (Tagamet) can increase the effectiveness of benzodiazepines.
- Calcium channel blockers, like Cardizem, can increase and prolong the effects of benzodiazepines.
- Grapefruit juice can increase the effects of benzodiazepines.
- Macrolide antibiotics (erythromycin, Biaxin) can increase and prolong the effects of benzodiazepines.
- Modifinil (Provigil) may reduce the effects of benzodiazepines.
- AIDS and antiretroviral drugs may increase and prolong the effects of benzodiazepines.

Central nervous system infections

Definition

The central nervous system, or CNS, comprises the brain, the spinal cord, and associated membranes. Under some circumstances, bacteria may enter areas of the CNS. If this occurs, abscesses or empyemas may be established.

Description

In general, the CNS is well defended against infection. The spine and brain are sheathed in tough, protective membranes. The outermost membrane, the dura mater, and the next layer, the arachnoid, entirely encase the brain and spinal cord. However, these defenses are not absolute. In rare cases, bacteria gain access to areas within the CNS.

Bacterial infection of the CNS can result in abscesses and empyemas (accumulations of pus). Abscesses have fixed boundaries, but empyemas lack definable shape and size. CNS infections are classified according to the location where they occur. For example, a spinal epidural **abscess** is located above the dura mater, and a cranial subdural **empyema** occurs between the dura mater and the arachnoid.

As pus and other material from an infection accumulate, pressure is exerted on the brain or spinal cord. This pressure can damage the nervous system tissue, possibly permanently. Without treatment, a CNS infection is fatal.

Causes and symptoms

Typically, bacterial invasion results from the spread of a nearby infection; for example, a chronic sinus or middle ear infection can extend beyond its initial site. Bacteria may also be conveyed to the CNS from distant sites of infection by the bloodstream. In rare cases, head **trauma** or surgical procedures introduce bacteria directly into the CNS. The source of infection cannot always be identified.

Specific symptoms of a CNS infection hinge on its exact location, but may include severe **headache** or back **pain**, weakness, sensory loss, and **fever**. An individual may report a stiff neck, nausea or **vomiting**, and tiredness or disorientation. There is a potential for seizures, **paralysis**, or **coma**.

Diagnosis

Examination

Physical symptoms, such as a fever and intense backache or a fever, severe headache, and stiff neck, raise the suspicion of a CNS infection.

Tests

Blood tests may indicate the presence of an infection but do not pinpoint its location. CT scans or MRI scans of the brain and spine can provide definitive diagnosis, with an MRI scan being the most sensitive.

Procedures

A **lumbar puncture** and analysis of the cerebrospinal fluid can help diagnose an epidural abscess; however, the procedure can be dangerous in cases of subdural empyema.

Treatment

A two-pronged approach is taken to treat CNS infections. First, antibiotic therapy against an array of potential infectious bacteria is begun. The second stage involves surgery to drain the infected site.

Although some CNS infections have been resolved with **antibiotics** alone, the more aggressive approach is often preferred. Surgery allows immediate relief of pressure on the brain or spinal cord, as well as an opportunity to collect infectious material for bacterial identification. Once the bacterial species is identified, drug therapy can be altered to a more specific antibiotic. Surgery may not be an option in some cases, such as when there are numerous sites of infection or when infection is located in an inaccessible area of the brain.

Prognosis

The fatality rate associated with CNS infections ranges from 10% to as high as 40%. Some survivors experience permanent CNS damage, resulting in partial paralysis, speech problems, or seizures. Rapid diagnosis and treatment are essential for a good prognosis. With prompt medical attention, an individual may recover completely.

Prevention

Treatment for pre-existing infections, such as sinus or middle ear infections, may prevent some cases of CNS infection. Since some CNS infections are of unknown origin, not all are preventable.

KEY TERMS

Abscess—A pus-filled area with definite borders.

Arachnoid—One of the membranes that sheathes the spinal cord and brain; the arachnoid is the second-layer membrane.

Cerebrospinal fluid—Fluid that is normally found in the spinal cord and brain. Abnormal levels of certain molecules in this fluid can indicate the presence of infection or damage to the central nervous system.

Computed tomography scan (CT)—Cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Dura mater—One of the membranes that sheathes the spinal cord and brain; the outermost layer.

Empyema—A pus-filled area with indefinite borders.

Lumbar puncture—A procedure in which a needle is inserted into the lower spine to collect a sample of cerebrospinal fluid.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Julia Barrett
REVISED BY LAURA JEAN CATALDO, RN, EdD

Central nervous system stimulants

Definition

Central nervous system (CNS) stimulants are medicines that stimulate the release of excitatory chemicals (primarily norepinephrine) from nerve cells, increasing brain and nerve activity.

Purpose

By increasing brain and nerve activity, these drugs increase wakefulness and speed thinking and physical processes.

The most commonly used central nervous system stimulant is **caffeine**.

Central nervous system stimulant drugs are used to treat daytime lethargy and sleepiness and, paradoxically, attention deficit and hyperactivity disorders, presumably by improving the ability to organize, focus, and concentrate mental activities.

Examples of central nervous system stimulants include modafinil (Provigil), sibutramine (Meridia), mistures of dextroamphetamines (Adderal), and methylphenidate (Ritalin, Concerta).

Description

With the exception of caffeine, which is available in a host of consumer products, these drugs are highly regulated, Class II **narcotics**.

These drugs are available in tablets, capsules, liquids, and patches.

Precautions

Studies on pregnant animals showed fetal teratogenic effects. They are not used in pregnant women unless the benefits outweigh potential risks. Nursing mothers pass small amounts of these drugs through their milk to babies.

Children with structural abnormalities or diseases of the heart are at risk for sudden death from taking these drugs. Before starting on them, they should have a careful cardiac evaluation.

Adults with heart abnormalities or diseases are at risk for sudden death, **stroke**, **heart attack**, or sudden death from taking these drugs. Before starting on them, they should have a careful cardiac evaluation.

WWW.BOOKBAZ.IR

These drugs can increase blood pressure and should be taken with caution by anyone who has **hyperthyroidism** or high blood pressure.

These drugs may increase manic episodes in people with bipolar manic-depressive disorder, and aggressive behavior, **psychosis** or thought disorders. They may increase the likelihood of seizures in people with **seizure disorder**.

These drugs should be used with caution by people who have a history of alcohol or drug abuse.

These drugs may produce drug-dependency and should not be withdrawn abruptly after prolonged use.

The brain adjusts and becomes tolerant to these drugs, so increasing doses are often needed to maintain the desired effects.

These drugs are not approved for use in children under the age of six; their use has been associated with growth retardation.

Risks

- angina, heart attack, and increased heart rate and arrhythmias
- high blood pressure
- agitation and restlessness
- confusion
- headache
- sleeplessness
- anger and aggression
- abdominal pain
- decreased appetite
- nausea, vomiting, and diarrhea
- anemia

Drug interactions

When taken with **monoamine oxidase inhibitors** (MAOI) (Marplan, Nardil, Parnate), these drugs can produce dangerously high blood pressure.

Withdrawal syndrome

Abruptly stopping these drugs after prolonged use may result in extreme **fatigue**, depression, and **sleep disorders**.

Central sleep apnea

Definition

Central **sleep apnea** is a disorder in which a person's ability to breathe starts and stops repeatedly while sleeping.

Demographics

Central sleep apnea is one of the rarest types of sleep apnea, accounting for less than 5% of all sleep apnea cases. Males are more likely than females to experience central sleep apnea. Central sleep apnea is also more common among older adults. People with a history of heart disorders, **stroke**, or **brain tumor** have a greater risk of developing central sleep apnea. The use of opioids is also associated with an increased risk of central sleep apnea.

Description

Sleep apnea is a disorder characterized by shallow or complete pauses in breathing while sleeping. Central sleep apnea is a type of sleep apnea characterized by a person's breathing stopping and starting repeatedly while sleeping because the brain does not send the proper signals to the muscles that control breathing. Central sleep apnea is different from the more common obstructive sleep apnea because it is caused by a problem with the brain signals the control breathing, rather than an obstruction in the upper airway. There are multiple types of central sleep apnea including Cheyne-Stokes breathing, idiopathic central sleep apnea, medical condition-induced central sleep apnea, drug-induced sleep apnea, high-altitude periodic breathing, and complex sleep apnea.

Risk factors

Risk factors associated with central sleep apnea include being male, being an older adult, suffering from heart disorders, stroke, or brain tumors, opioid use, and being treated with continuous positive airway pressure when suffering from obstructive sleep apnea. Sleeping at a higher altitude than typical for a person can also cause central sleep apnea, however, this is transient and disappears once the person returns to a lower altitude.

Causes and symptoms

Central sleep apnea is not caused by an obstruction unlike obstructive sleep apnea, but instead by the brain failing to transmit signals to the muscles used in

breathing. The different types of central sleep apnea have their own specific causes.

- Cheyne-Stokes breathing. Cheyne-Stokes breathing is associated with stroke or congestive heart failure. Symptoms of Cheyne-Stokes breathing are a rhythmic increase and then decrease in airflow and breathing effort. Central sleep apnea occurs when there is a total lack of airflow.
- Idiopathic central sleep apnea. Idiopathic central sleep apnea is the name given to central sleep apnea not associated with another disease. The cause is of this type of central sleep apnea is unknown. It is characterized by repeated breaks in breathing effort and airflow.
- Medical condition-induced central sleep apnea. Medical condition-induced central sleep apnea is associated with heart failure and stroke in addition to any type of damage to the part of the brainstem that controls breathing.
- Drug-induced sleep apnea. Certain types of medications, such as opioids, can be associated with central sleep apnea. These medications, (e.g., morphine, codeine, oxycodone) affect the central nervous system and may cause changes in a person's breathing behavior including complete stopping of breathing.
- High-altitude periodic breathing. People sleeping at altitudes higher than they are used to, typically above 15,000 feet (4,500 m) may suffer from high-altitude periodic breathing. This is characterized by alternating between underbreathing and rapid breathing. This type of sleep apnea goes away once the person is back at a lower altitude.
- Complex sleep apnea. People being treated for obstructive sleep apnea with continuous positive airway pressure may develop central sleep apnea. The name complex sleep apnea is used because the person suffers from both obstructive and central sleep apnea.

Other general symptoms of central sleep apnea include **snoring**, morning headaches, **insomnia**, hypersomnia (excessive tiredness), **shortness of breath** that goes away once sitting, and abrupt awakening accompanied by shortness of breath. When sleep apnea is due to a neurological condition, symptoms may include voice changes, weakness or numbness of the body, and difficulty swallowing.

Diagnosis

Many doctors are able to diagnose a patient with central sleep apnea by evaluating the signs and symptoms shown. Others may refer a patient to a sleep disorder center. A **polysomnography** test is a common diagnostic tool used at sleep disorder centers. During a polysomnography, a person is connected to equipment that monitors the heart, lungs, brain, arm and leg movements, blood oxygen levels, and breathing patterns while the person is sleeping. By monitoring a patient using this method, doctors and sleep specialists are better able to determine what condition a patient is suffering from. Other diagnostic methods may include echocardiograms, MRI of the spine or neck, and lung function studies.

KEY TERMS

Continuous Positive Airway Pressure (CPAP)—A type of treatment that provides continuous pressure at a constant flow against exhalation to keep an airway open. CPAP is used for people with breathing problems such as sleep apnea.

Hypersomnia—Excessive and reoccurring daytime sleepiness.

Idiopathic—of unknown origin; without a known cause.

Insomnia—A sleep disorder characterized by inability either to fall asleep or to stay asleep.

Opioid—Any morphine-like synthetic narcotic that produces the same effects as drugs derived from the opium poppy (opiates), such as pain relief, sedation, constipation and respiratory depression.

Stroke—Irreversible damage to the brain caused by insufficient blood flow to the brain as the result of a blocked artery. Damage can include loss of speech or vision, paralysis, cognitive impairment, and death.

Treatment

There are various treatments for central sleep apnea and patients should work with their doctor to find the best treatment for their particular situation. Adaptive servo-ventilation uses a machine to regulate breathing and prevent pauses. Bilevel positive airway pressure, is a device that increases pressure when a person inhales and lowers the pressure when a person exhales. This machine can be set to automatically deliver a breath if the person has not taken a breath on his or her own within a specified time. Supplemental oxygen and medications that stimulate breathing are also sometimes prescribed for central sleep apnea. Exact treatment will vary depending on the type of central sleep apnea a patient suffers from.

WWW.BOOKBAZ.IR

- Medical condition-induced central sleep apnea. Treating the medical condition that causes the breathing problem may improve or cure central sleep apnea.
- Drug-induced sleep apnea. If medication is believed to be the cause of a person's sleep apnea, reducing the amount taken may stop all symptoms of central sleep apnea.
- High-altitude periodic breathing. Sleep apnea associated with higher altitudes has been found to go away as soon as the person is back at a lower altitude. Acetazolamide may be prescribed for people who suffer from central sleep apnea related to high altitude.
- Complex sleep apnea. Obstructive sleep apnea is often treated through wearing a mask over the nose while sleeping. This treatment has been found to trigger central sleep apnea in some people. Patients who suffer from complex sleep apnea should work with their doctor to find a proper fitting mask that lessens the chance of central sleep apnea from being triggered.

Prognosis

Prognosis depends on the medical condition causing central sleep apnea. If the medical condition can be treated, the sleep apnea is often also treated. In general, the outlook for people suffering from central sleep apnea is good, especially those who suffer from idiopathic sleep apnea.

Prevention

There are various ways to reduce the likelihood of developing central sleep apnea. Preventing medical conditions that are believed to cause central sleep apnea reduces the likelihood of suffering from central sleep apnea. People who experience high-altitude periodic breathing should limit the time they spend sleeping at high altitudes. People who suffer from drug-induced sleep apnea should talk to their physician about reducing the amount of the sleep apnea-causing drug they are taking.

Cephalosporins

Definition

Cephalosporins are a type of antibiotic, a medication that kills bacteria or prevents their growth.

Purpose

Cephalosporins are used to treat bacterial infections in different parts of the body—for example, the ears, nose, throat, lungs, sinuses, or skin. Physicians may prescribe these drugs to treat **pneumonia**, **strep throat**, staph infections, **tonsillitis**, **bronchitis**, or

gonorrhea. These drugs will *not* work for infections caused by viruses, including colds and flu.

Cephalosporins are also commonly used for surgical prophylaxis—the prevention of bacterial infection during or immediately after surgery. For this purpose, a single injection may be given during the surgical procedure. In some cases, the cephalosporin may be continued for 24 to 48 hours after surgery. If, in spite of all precautions, an infection develops, the **antibiotics** may be continued until the infection has resolved.

Description

Examples of cephalosporins include cefaclor (Ceclor), cefadroxil (Duricef), cefazolin (Ancef, Kefzol, Zolicef), cefixime (Suprax), cefoxitin (Mefoxin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), cefuroxime (Ceftin), and cephalexin (Keflex). These medicines are available only with a physician's prescription. They are sold in tablet, capsule, liquid, and injectable forms.

Cephalosporins are sometimes categorized as first, second, or third generation. Each generation is effective against more types of bacteria than the one before it. In addition, each subsequent generation is better at reaching the central nervous system (the brain and spinal cord).

Cephalosporins are chemically similar to **penicillins** and to other types of antibiotics called cephamycins.

Recommended dosage

The recommended dosage depends on the type of cephalosporin. The physician who prescribed the drug or the pharmacist who filled the prescription should be consulted for the correct dosage.

Prescriptions

Cephalosporins should be taken exactly as directed by the physician. The patient should never take larger, smaller, more frequent, or less frequent doses than prescribed. The drug should be taken for exactly as long as directed, and all of the medicine prescribed should be taken. The infection may not clear up completely if too little medicine is taken. Taking this medicine for too long, on the other hand, may open the door to new infections that do not respond to the drug. No amount of the drug should be saved to take for future infections, because the medicine may not be right for other kinds of infections, even if the symptoms are the same.

Some cephalosporins work best when taken on an empty stomach. Others should be taken after meals. The physician who prescribed the medicine or the pharmacist who filled the prescription should give instructions as to how to take the medicine.

Surgical prophylaxis

When given for surgical **prophylaxis**, it used to be common practice to give a dose of a cephalosporin as soon as the patient has been called to the operating room. More recently, the practice has been to give a single dose during the surgical procedure. This works just as well as the "on-call" dose, and lowers the amount of antibiotic that the patient must take.

Precautions

Most precautions apply to cephalosporins prescribed to treat infections, particularly if the cephalosporins are given by mouth. Risks are less when cephalosporins are given as a single intravenous dose prior to or during surgery.

Certain cephalosporins should not be combined with alcohol or with medicines that contain alcohol. Abdominal or stomach cramps, nausea, **vomiting**, facial flushing, and other symptoms may result within 15–30 minutes and may last for several hours. Alcoholic beverages as well as other medicines that contain alcohol should be avoided while being treated with cephalosporins and for several days after treatment ends.

Special conditions

People with certain medical conditions or who are taking certain other medicines can have problems if they take cephalosporins. Before taking these drugs, be sure to let the physician know about any other existing conditions.

ALLERGIES. Severe allergic reactions to this medicine may occur. Anyone who is allergic to cephalosporins of any kind should not take other cephalosporins. Anyone who is allergic to penicillin should check with a physician before taking any cephalosporin. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances. The type of allergic reaction should be discussed in detail, since some people have reactions to a drug that are not truly allergies. These people may be able to take cephalosporins safely.

DIABETES. Some cephalosporins may cause false positive results on urine sugar tests for diabetes. People with diabetes should check with their physicians to see if they need to adjust their medication or their **diets**.

WWW.BOOKBAZ.IR

PHENYLKETONURIA. Oral suspensions of cefprozil contain phenylalanine. People with **phenylketonuria** (PKU) should consult a physician before taking this medicine.

PREGNANCY. Women who are pregnant or who may become pregnant should check with their physicians before using cephalosporins.

BREAST FEEDING. Cephalosporins may pass into breast milk. Women who are breast feeding and who need to take this medicine should check with their physicians. They may need to stop breast feeding until treatment is finished.

OTHER MEDICAL CONDITIONS. Before using cephalosporins, people with any of these medical problems should make sure their physicians are aware of their conditions:

- history of stomach or intestinal problems, especially colitis—cephalosporins may cause colitis in some people
- kidney problems (dose may need to be lowered)
- bleeding problems—cephalosporins may increase the chance of bleeding in people with a history of bleeding problems
- liver disease (dose may need to be lowered)

Side effects

The patient should get medical attention immediately if any of these symptoms develop while taking cephalosporins:

- shortness of breath
- pounding heartbeat
- skin rash or hives
- severe cramps or pain in the stomach or abdomen
- fever
- severe watery or bloody diarrhea (may occur up to several weeks after stopping the drug)
- unusual bleeding or bruising

Other rare side effects may occur. Anyone who has unusual symptoms during or after treatment with cephalosporins should contact his or her physician.

Interactions

Some cephalosporins cause **diarrhea**. Certain diarrhea medicines, such as diphenoxylate-atropine (Lomotil), may make the problem worse. Check with a physician before taking any medicine for diarrhea caused by taking cephalosporins.

Birth control pills may not work properly when taken at the same time as cephalosporins. To prevent **pregnancy**, other methods of birth control in addition to the pills are advised while taking cephalosporins.

Cephalosporins may also interact with other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes cephalosporins should let the physician know all other medicines he or she is taking.

Surgery

Taking cephalosporins with certain other drugs may increase the risk of excess bleeding. Among the drugs that may have this effect when taken with cephalosporins are:

- blood-thinning drugs (anticoagulants) such as warfarin (Coumadin)
- blood viscosity-reducing medicines such as pentoxifylline (Trental)
- the antiseizure medicines divalproex (Depakote) and valproic acid (Depakene)

KEY TERMS

Antibiotic—A medicine used to treat infections.

Bronchitis—Inflammation of the air passages of the lungs.

Colitis—Inflammation of the colon (large bowel).

Gonorrhea—A sexually transmitted disease (STD) that causes infection in the genital organs and may cause disease in other parts of the body.

Phenylketonuria (PKU)—A genetic disorder in which the body lacks an important enzyme. If untreated, the disorder can lead to brain damage and intellectual disability.

Pneumonia—A disease in which the lungs become inflamed. Pneumonia may be caused by bacteria, viruses, or other organisms, or by physical or chemical irritants.

Prophylaxis—A measure designed to preserve health and/or prevent the spread of disease.

Staph infection—Infection with *Staphylococcus* bacteria. These bacteria can infect any part of the body.

Strep throat—A sore throat caused by infection with *Streptococcus* bacteria. Symptoms include sore throat, chills, fever, and swollen lymph nodes in the neck.

Tonsillitis—Inflammation of a tonsil, a small mass of tissue in the throat.

Cerebral abscess *see* **Brain abscess**

Cerebral amyloid angiopathy

Definition

Cerebral amyloid angiopathy (CAA) is also known as congophilic angiopathy or cerebrovascular **amyloidosis**. It is a disease of small blood vessels in the brain in which deposits of amyloid protein in the vessel walls may lead to **stroke**, brain hemorrhage, or **dementia**. Amyloid protein resembles a starch and is deposited in tissues during the course of certain chronic diseases.

Description

CAA may affect patients over age 45, but is most common in patients over age 65, and becomes more common with increasing age. Men and women are equally affected. In some cases, CAA is sporadic but it may also be inherited as an autosomal dominant condition (a form of inheritance in which only one copy of a gene coding for a disease need be present for that disease to be expressed; if either parent has the disease, a child has a 50% chance of inheriting the disease). CAA is responsible for 5–20% of brain hemorrhage, and up to 30% of lobar hemorrhages localized to one lobe of the brain. CAA may be found during an **autopsy** in over one-third of persons over age 60, even though they may not have had brain hemorrhage, stroke, or other manifestations of the disease during life. In Alzheimer's disease, CAA is more common than in the general population, and may occur in more than 80% of patients over age 60.

Causes and symptoms

The cause of amyloid deposits in blood vessels in the brain in sporadic CAA is not known. In hereditary CAA, genetic defects, typically on chromosome 21, allow accumulation of amyloid, a protein made up of units called beta-pleated sheet fibrils. The fibrils tend to clump together, so that the amyloid cannot be dissolved and builds up in the brain blood vessel walls. One form of amyloid fibril subunit proteins is the amyloid beta protein.

Different theories have been suggested for the source of amyloid beta protein in the brain. The systemic theory suggests that amyloid beta protein in the blood stream is deposited in blood vessels in the brain, causing weakness in the blood vessel wall and breakdown in the blood-brain barrier. Normally, the blood-brain barrier keeps proteins and other large molecules from escaping from the blood vessel to the brain tissue. When there is breakdown of the blood-brain barrier, amyloid beta protein leaks through the blood vessel wall, and is deposited in the brain substance, where it forms an abnormal structure called a neuritic plaque.

A second, more likely theory is that amyloid fibrils that form amyloid beta protein are produced by perivascular microglia, or support cells in contact with the brain blood vessel wall. The third theory is that the brain tissue gives rise to amyloid beta protein. Both the nerve cells and the glia are known to produce amyloid precursor protein, which increases with **aging** and with cell **stress**.

Bleeding into the brain may occur as tiny blood vessels carrying amyloid deposits become heavier and more brittle, and are therefore more likely to burst with minor **trauma** or with fluctuating blood pressure. Aneurysms, or ballooning of the blood vessel wall,

WWW.BOOKBAZ.IR

may develop, and may also rupture as the stretched wall becomes thinner and is under more pressure. Amyloid deposits may destroy smooth muscle cells or cause inflammation in the blood vessel wall. This may also cause the blood vessel to break more easily.

The most common form of CAA is the sporadic form associated with aging. This type of CAA usually causes lobar hemorrhage, which may recur in different lobes of the brain. The frontal lobe (behind the forehead) and parietal lobe (behind the frontal lobe) are most often affected; the temporal lobe (near the temple) and occipital lobe (at the back of the brain) are affected less often; and the cerebellum (under the occipital lobe) is rarely affected. Approximately 10–50% of hemorrhages in sporadic CAA involve more than one lobe.

Symptoms of lobar hemorrhage in CAA include sudden onset of **headache**, neurologic symptoms such as weakness, sensory loss, visual changes, or speech problems, depending on which lobe is involved; and decreased level of consciousness (a patient who is difficult to arouse), nausea, and **vomiting**. Sporadic CAA may be associated with symptoms unrelated to lobar hemorrhage. Petechial hemorrhages (tiny hemorrhages involving many small vessels) may produce recurrent, brief neurologic symptoms secondary to seizures or decreased blood flow, or may produce rapidly progressive dementia (loss of memory and other brain functions) that worsens in distinct steps rather than gradually. Over 40% of patients with hemorrhage secondary to CAA also have dementia.

Genetic factors play a role in certain types of CAA and in diseases associated with CAA:

- Dutch type of hereditary cerebral hemorrhage with amyloidosis (build up of amyloid protein in blood vessels): autosomal dominant, with a genetic mutation involving the amyloid precursor protein. Onset is at age 40–60 with headaches, brain hemorrhage often in the parietal lobe, strokes, and dementia. More than half of patients die from their first hemorrhage. Patients with the Dutch type of CAA may produce an abnormal anticoagulant, or blood thinner, which makes hemorrhage more likely.
- Flemish type of hereditary cerebral hemorrhage with amyloidosis: autosomal dominant, with a mutation involving the amyloid precursor protein. Symptoms include brain hemorrhage or dementia.
- Familial Alzheimer's disease: autosomal dominant, comprising 5–10% of all Alzheimer's disease cases (a brain disease in which death of nerve cells leads to progressive dementia).
- Down syndrome: caused by trisomy 21 (three rather than two copies of chromosome 21), causing excess amyloid precursor protein gene. Children with Down syndrome are mentally handicapped and may have heart problems.
- Icelandic type of hereditary cerebral hemorrhage with amyloidosis: autosomal dominant, with mutation in the gene coding for cystatin C. Symptoms often begin at age 30–40 with multiple brain hemorrhages, dementia, paralysis (weakness), and death in 10–20 years. Headache occurs in more than half of patients, and seizures occur in one-quarter. Unlike most other forms of CAA, most hemorrhages involve the basal ganglia deep within the brain. (Basal ganglia are islands of tissues in the cerebellum part of the brain.)
- Familial oculo-leptomeningeal amyloidosis: autosomal dominant with unknown gene defect(s), described in Japanese, Italian, and North American families. Symptoms can include dementia, ataxia (problems with coordination), spasticity (limb stiffness), strokes, seizures, peripheral neuropathy (disease affecting the nerves supplying the limbs), migraine, spinal cord problems, blindness, and deafness. Brain hemorrhage is rare as the amyloid protein is deposited in blood vessels in the eye and meninges (brain coverings), but not in the brain itself. In Italian families with the disease, patients may be affected as early as 20–30 years of age.
- British type of familial amyloidosis: autosomal dominant with unknown gene defect(s), associated with progressive dementia, spasticity, and ataxia. Brain stem, spinal cord, and cerebellum all exhibit amyloid deposits, but hemorrhage typically does not occur.

Diagnosis

As in most neurologic diseases, diagnosis is made most often from the patient's history, with careful inquiry into family history and the patient's onset and pattern of symptoms, as well as neurologic examination. Brain computed tomography scan (CT) or **magnetic resonance imaging** (MRI) may identify lobar hemorrhage, stroke, or petechial hemorrhages, and are important in excluding arteriovenous malformation, **brain tumor**, or other causes of hemorrhage. **Angiography** (x-ray study of the interior of blood vessels and the heart) is not helpful in diagnosis of CAA, but may be needed to exclude aneurysm. **Brain biopsy** (surgical removal of a small piece of brain tissue) may show characteristic amyloid deposits, but is rarely performed, as the risk may not be justifiable in the absence of effective treatment for CAA. If diagnosis is uncertain, biopsy may be needed to rule out

KEY TERMS

Amyloid—Amyloid protein resembles a starch and is deposited in tissues during the course of certain chronic diseases.

Ataxia—Problems with coordination and walking.

Autosomal dominant—A form of inheritance in which only one copy of a gene coding for a disease need be present for that disease to be expressed. If either parent has the disease, a child has a 50% chance of inheriting the disease.

Chromosome—A cellular structure containing genetic information in the form of DNA.

Dementia—Loss of memory and other higher functions, such as thinking or speech, lasting six months or more.

Hemorrhage—Bleeding, or escape of blood through ruptured or unruptured blood vessel walls.

Lobar hemorrhage—Bleeding into one of the lobes of the brain.

Seizure—Epileptic convulsion, fit, or attack.

Spasticity—Limb stiffness related to disease of the brain or spinal cord.

Sporadic—A form of disease found in persons without a family history of the disease.

Stroke—Sudden neurological deficit related to impaired blood supply to the brain.

conditions which are potentially treatable. Definite diagnosis requires microscopic examination of brain tissue, either at biopsy, at autopsy, or at surgery when brain hemorrhage is drained. **Lumbar puncture** to examine cerebrospinal fluid proteins may show characteristic abnormalities, but is not part of the routine exam. In familial forms, genetic analysis may be helpful.

CAA with hemorrhage must be distinguished from other types of brain hemorrhage. In CAA, hemorrhage typically occurs in the lobar region, often ruptures into the subarachnoid space between the brain and its coverings, and occurs at night. In hemorrhage related to high blood pressure, hemorrhage is usually deeper within the brain, ruptures into the ventricles or cavities deep inside the brain, and occurs during daytime activities. Other causes of brain hemorrhage are **arteriovenous malformations**, trauma, aneurysms, bleeding into a brain tumor, **vasculitis** (inflammation of blood vessels), or bleeding disorders.

Treatment

Although there is no effective treatment for the underlying disease process of CAA, measures can be taken to prevent brain hemorrhage in patients diagnosed with CAA. High blood pressure should be treated aggressively, and even normal blood pressure can be lowered as much as tolerated without side effects from medications. Blood thinners such as Coumadin, antiplatelet agents such as **aspirin**, or medications designed to dissolve **blood clots** may cause hemorrhage in patients with CAA, and should be avoided if possible. If these medications are required for other conditions, such as **heart disease**, the potential benefits must be carefully weighed against the increased risks.

Seizures, or recurrent neurologic symptoms thought to be seizures, should be treated with anti-epileptic drugs, although Depakote (**sodium** valproate) should be avoided because of its antiplatelet effect. Anti-epileptic drugs are sometimes given to patients with large lobar hemorrhage in an attempt to prevent seizures, although the benefit of this is unclear.

Once brain hemorrhage has occurred, the patient should be admitted to a hospital (ICU) for neurologic monitoring and control of increased pressure within the brain, blood pressure control, and supportive medical care. Antiplatelet agents and blood thinners should be discontinued and their effects reversed, if possible. Surgery may be needed to remove brain hemorrhage, although bleeding during surgery may be difficult to control.

CAA may be rarely associated with cerebral vasculitis, or inflammation of the blood vessel walls. In these cases treatment with **steroids** or immune system suppressants may be helpful. Without tissue examination, vasculitis cannot be diagnosed reliably, and probably coexists with CAA too rarely to justify steroid treatment in most cases.

Prognosis

Since CAA is associated with progressive blood vessel degeneration, and since there is no effective treatment, most patients have a poor prognosis. Aggressive neurosurgical management allows increased survival following lobar hemorrhage, but 20–90% of patients die from the first hemorrhage or its complications,

WWW.BOOKBAZ.IR

which include progression of hemorrhage, brain **edema** (swelling) with herniation (downward pressure on vital brain structures), seizures, and infections such as **pneumonia**. Many survivors have persistent neurologic deficits related to the brain lobe affected by hemorrhage, and are at risk for additional hemorrhages, seizures, and dementia. Prognosis is worse in patients who are older, or who have larger hemorrhages or recurrent hemorrhages within a short time.

Cerebral aneurysm

Definition

A cerebral aneurysm occurs at a weak point in the wall of a blood vessel (artery) that supplies blood to the brain. Because of the flaw, the artery wall bulges outward and fills with blood. This bulge is called an aneurysm. An aneurysm can rupture, spilling blood into the surrounding body tissue. A ruptured cerebral aneurysm can cause permanent brain damage, disability, or death.

Description

A cerebral aneurysm can occur anywhere in the brain. Aneurysms can have several shapes. The saccular aneurysm, once called a berry aneurysm, resembles a piece of fruit dangling from a branch. Saccular aneurysms are usually found at a branch in the blood vessel where they balloon out by a thin neck. Saccular cerebral aneurysms most often occur at the branch points of large arteries at the base of the brain. Aneurysms may also take the form of a bulge in one wall of the artery—a lateral aneurysm—or a widening of the entire artery—a fusiform aneurysm.

The greatest danger of aneurysms is rupture. Approximately 50–75% of stricken people survive an aneurysmal rupture. A ruptured aneurysm spills blood into the brain or into the fluid-filled area that surrounds the brain tissue. Bleeding into this area, called the subarachnoid space, is referred to as **subarachnoid hemorrhage** (SAH). About 25,000 people suffer a SAH each year. It is estimated that people with unruptured aneurysm have an annual 1–2% risk of hemorrhage. Under age 40, more men experience SAH. After age 40, more women than men are affected.

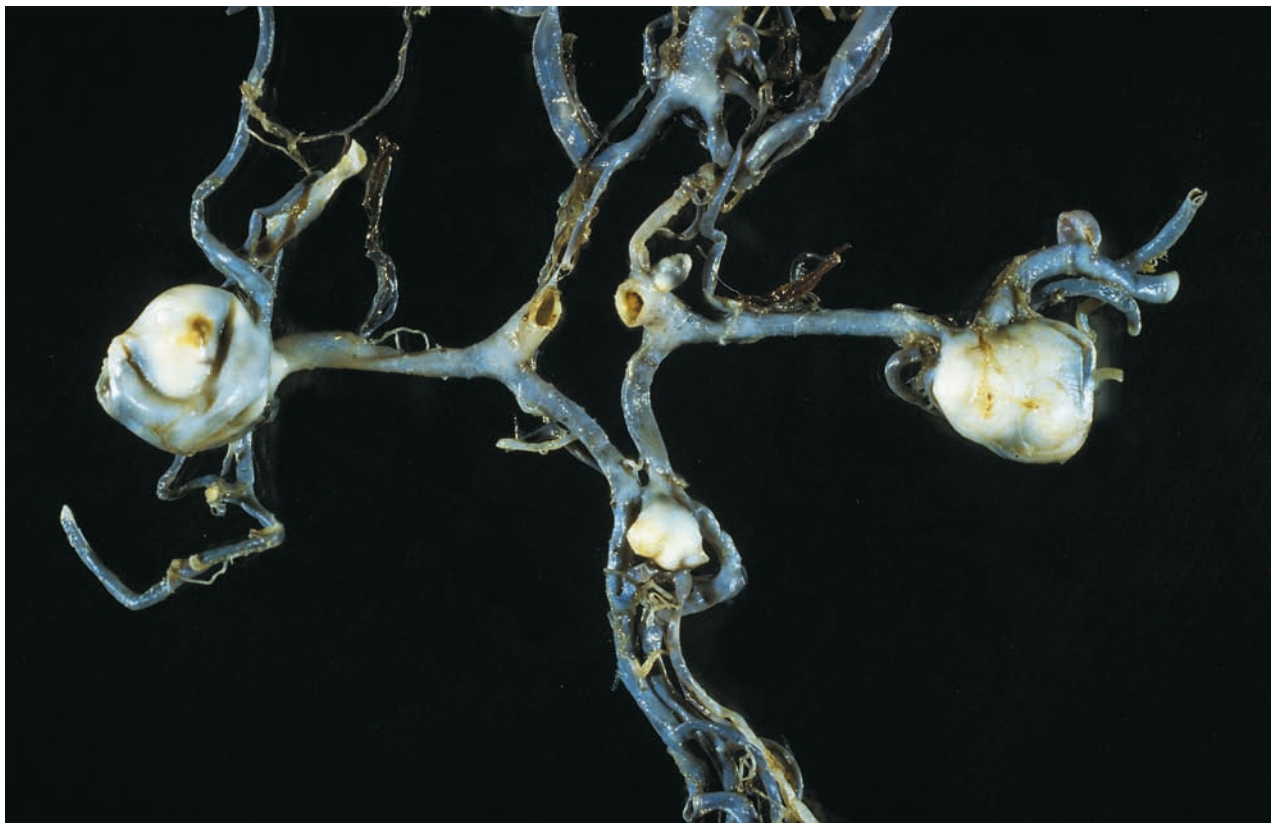
Most people who have suffered a SAH from a ruptured aneurysm did not know that the aneurysm even existed. Based on **autopsy** studies, medical researchers estimate that 1–5% of the population has some type of cerebral aneurysm. Aneurysms rarely occur in the very young or the very old; about 60% of aneurysms are diagnosed in people between ages 40 and 65.

Some aneurysms may have a genetic link and run in families. The genetic link has not been completely proven and a pattern of inheritance has not been determined. Some studies seem to show that first-degree relatives of people who suffered aneurysmal SAH are more likely to have aneurysms themselves. These studies reported that such immediate family members were four times more likely to have aneurysms than the general population. Other studies do not confirm these findings. Better evidence links aneurysms to certain rare diseases of the connective tissue. These diseases include **Marfan syndrome**, **pseudoxanthoma elasticum**, **Ehlers-Danlos syndrome**, and fibromuscular dysplasia. **Polycystic kidney disease** is also associated with cerebral aneurysms.

These diseases are also associated with an increased risk of aneurysmal rupture. Certain other conditions raise the risk of rupture, too. Most aneurysms that rupture are a half-inch or larger in diameter. Size is not the only factor, however, because smaller aneurysms also rupture. Cigarette **smoking**, excessive alcohol consumption, and recreational drug use (for example, use of cocaine) have been linked with an increased risk. The role, if any, of high blood pressure has not been determined. Some studies have implicated high blood pressure in aneurysm formation and rupture, but people with normal blood pressure also experience aneurysms and SAHs. High blood pressure may be a risk factor but not the most important one. **Pregnancy**, labor, and delivery also seem to increase the possibility that an aneurysm might rupture, but not all doctors agree. Physical exertion and use of **oral contraceptives** are not suspected causes for aneurysmal rupture.

Causes and symptoms

Cerebral aneurysms can be caused by brain **trauma**, infection, hardening of the arteries (atherosclerosis), or abnormal rapid cell growth (neoplastic disease), but most seem to arise from a congenital, or developmental, defect. These congenital aneurysms occur more frequently in women. Whatever the cause



Three aneurysms can be seen in this section of a cerebral artery removed from a human brain. *(© Martin Rotker/Phototake.—All rights reserved.)*

may be, the inner wall of the blood vessel is abnormally thin and the pressure of the blood flow causes an aneurysm to form.

Most aneurysms go unnoticed until they rupture. However, 10–15% of unruptured cerebral aneurysms are found because of their size or their location. Common warning signs include symptoms that affect only one eye, such as an enlarged pupil, a drooping eyelid, or **pain** above or behind the eye. Other symptoms are a localized **headache**, unsteady gait, a temporary problem with sight, double vision, or numbness in the face.

Some aneurysms bleed occasionally without rupturing. Symptoms of such an aneurysm develop gradually. The symptoms include headache, nausea, **vomiting**, neck pain, black-outs, ringing in the ears, **dizziness**, or seeing spots.

Eighty to ninety percent of aneurysms are not diagnosed until after they have ruptured. Rupture is not always a sudden event. Nearly 50% of patients who have aneurysmal SAHs also experience "the warning leak phenomenon." Persons with warning leak symptoms have sudden, atypical headaches that occur days or weeks before the actual rupture. These headaches are referred to as sentinel headaches. Nausea, vomiting, and dizziness may accompany sentinel headaches. Unfortunately, these symptoms can be confused with tension headaches or migraines, and treatment can be delayed until rupture occurs.

When an aneurysm ruptures, most victims experience a sudden, extremely severe headache. This headache is typically described as the worst headache of the victim's life. **Nausea and vomiting** commonly accompany the headache. The person may experience a short loss of consciousness or prolonged **coma**. Other common signs of a SAH include a stiff neck, **fever**, and a sensitivity to light. About 25% of victims experience neurological problems linked to specific areas of the brain, swelling of the brain due to fluid accumulation (**hydrocephalus**), or seizure.

Diagnosis

Based on the clinical symptoms, a doctor will run several tests to confirm an aneurysm or an SAH. A computed tomography scan (CT) of the head is the initial procedure. A **magnetic resonance imaging** test

WWW.BOOKBAZ.IR

(MRI) may be done instead of a CT scan. MRI, however, is not as sensitive as CT for detecting subarachnoid blood. A CT scan can determine whether there has been a hemorrhage and can assist in pinpointing the location of the aneurysm. The scan is most useful when it is done within 72 hours of the rupture. Later scans may miss the signs of hemorrhage.

If the CT scan is negative for a hemorrhage or provides an unclear diagnosis, the doctor will order a cerebrospinal fluid (CSF) analysis, also called a **lumbar puncture**. In this procedure, a small amount of cerebrospinal fluid is removed from the lower back and examined for traces of blood and blood-breakdown products. If this test is positive, cerebral **angiography** is used to map the brain's blood vessels and the damaged area. The angiography is done to pinpoint the aneurysm's location. About 15% of people who experience SAH have more than one aneurysm. For this reason, angiography should include both the common carotid artery that feeds the front of the brain and the vertebral artery that feeds the base of the brain. Occasionally, the angiography fails to find the aneurysm and must be repeated. If seizures occur, **electroencephalography** (EEG) may be used to measure the electrical activity of the brain.

Treatment

Unruptured aneurysm

If an aneurysm has not ruptured and is not causing any symptoms, it may be left untreated. Because there is a 1–2% chance of rupture per year, the cumulative risk over a number of years may justify surgical treatment. However, if the aneurysm is small or in a place that would be difficult to reach, or if the person who has the aneurysm is in poor health, the surgical treatment may be a greater risk than the aneurysm. Risk of rupture is higher for people who have more than one aneurysm. Unruptured aneurysm would probably be treated with a surgical procedure called the clip ligation, as described in the following text.

Ruptured aneurysm

The primary treatment for a ruptured aneurysm involves stabilizing the victim's condition, treating the immediate symptoms, and promptly assessing further treatment options, especially surgical procedures. The patient may require mechanical ventilation, oxygen, and fluids. Medications may be given to prevent major secondary complications such as seizures, rebleeding, and vasospasm (narrowing of the affected blood vessel). Vasospasm decreases blood flow to the brain and causes the death of nerve cells. A drug such as nimodipine (Nimotop) may help prevent vasospasm by relaxing the smooth muscle tissue of the arteries. Even with treatment, however, vasospasm may cause **stroke** or death.

To prevent further hemorrhage from the aneurysm, it must be removed from circulation. In general, surgical procedures should be performed as soon as possible to prevent rebleeding. The chances that aneurysm will rebleed are greatest in the first 24 hours, and vasospasm usually does not occur until 72 hours or more after rupture. If the patient is in poor condition or if there is vasospasm or other complication, surgical procedures may be delayed. The preferred surgical method is a clip ligation in which a clip is placed around the base of the aneurysm to block it off from circulation. Surgical coating, wrapping, or trapping of the aneurysm may also be performed. These procedures do not completely remove the aneurysm from circulation, however, and there is some risk that it may rebleed in the future. Newer techniques that look promising include balloon embolization, a procedure that blocks the aneurysm with an inflatable membrane introduced by means of a catheter inserted through the artery.

Prognosis

An unruptured aneurysm may not cause any symptoms over an entire lifetime. Surgical clip ligation will ensure that it won't rupture, but it may be better to leave the aneurysm alone in some cases. Familial cerebral aneurysms may rupture earlier than those without a genetic link.

The outlook is not as good for a person who suffers a ruptured aneurysm. Fifteen to twenty-five percent of people who experience a ruptured aneurysm do not survive. An additional 25–50% die as a result of complications associated with the hemorrhage. Of the survivors, 15–50% suffer permanent brain damage and disability. These conditions are caused by the death of nerve cells. Nerve cells can be destroyed by the hemorrhage itself or by complications from the hemorrhage, such as vasospasm or hydrocephalus. Hydrocephalus, a dilatation (expansion) of the fluid-filled cavity surrounding the brain, occurs in about 15% of cases. Immediate medical treatment is vital to prevent further complications and brain damage in those who survive the initial rupture. Patients who survive SAH and aneurysm clipping are unlikely to die from events related to SAH.

Prevention

There are no known methods to prevent an aneurysm from forming. If an aneurysm is discovered before

KEY TERMS

Congenital—Existing at birth.

Ehlers-Danlos syndrome—A rare inheritable disease of the connective tissue marked by very elastic skin, very loose joints, and very fragile body tissue.

Embolization—A technique to stop or prevent hemorrhage by introducing a foreign mass, such as an air-filled membrane (balloon), into a blood vessel to block the flow of blood.

Fibromuscular dysplasia—A disorder that causes unexplained narrowing of arteries and high blood pressure.

Magnetic resonance angiography—A noninvasive diagnostic technique that uses radio waves to map the internal anatomy of the blood vessels.

Marfan syndrome—An inheritable disorder that affects the skeleton, joints, and blood vessels. Major indicators are excessively long arms and legs, lax joints, and vascular defects.

Nimodipine (Nimotop)—A calcium-channel blocker, that is, a drug that relaxes arterial smooth muscle by slowing the movement of calcium across cell walls.

Polycystic kidney disease—An abnormal condition in which the kidneys are enlarged and contain many cysts.

Pseudoxanthoma elasticum—A hereditary disorder of the connective, or elastic, tissue marked by premature aging and breakdown of the skin and degeneration of the arteries that leads to hemorrhages.

Subarachnoid hemorrhage (SAH)—Loss of blood into the subarachnoid space, the fluid-filled area that surrounds the brain tissue.

Vasospasm—Narrowing of a blood vessel caused by a spasm of the smooth muscle of the vessel wall.

it ruptures, it may be surgically removed. CT or MRI angiography may be recommended for relatives of patients with familial cerebral aneurysms.

Cerebral angiography *see* **Angiography**

Cerebral palsy

Definition

Cerebral palsy (CP) is the term used for a group of nonprogressive disorders of movement and posture caused by abnormal development of, or damage to, motor control centers of the brain. CP is caused by events before, during, or after birth. The abnormalities of muscle control that define CP are often accompanied by other neurological and physical abnormalities.

Demographics

United Cerebral Palsy (UCP) estimates that some 764,000 children and adults in the United States display one or more of the symptoms of cerebral palsy. Approximately 10,000 babies and infants are diagnosed with the condition each year. In addition, some 1,500 preschool age children are recognized each year to have cerebral palsy.

Description

Voluntary movement (walking, grasping, chewing, etc.) is primarily accomplished using muscles that are attached to bones, known as the skeletal muscles. Control of the skeletal muscles originates in the cerebral cortex, the largest portion of the brain. Palsy means **paralysis**, but may also be used to describe uncontrolled muscle movement or tension (hypertonia). Therefore, cerebral palsy encompasses any disorder of abnormal movement and paralysis caused by abnormal function of the cerebral cortex. In truth, however, CP does not include conditions due to progressive disease or degeneration of the brain. For this reason, CP is also referred to as static (nonprogressive) **encephalopathy** (disease of the brain). Also excluded from CP are any disorders of muscle

WWW.BOOKBAZ.IR

control that arise in the muscles themselves and/or in the peripheral nervous system (nerves outside the brain and spinal cord).

CP is not a specific condition, but is more accurately considered a description of a broad but defined group of neurological and physical problems.

The severity of CP is quite variable. Some people with CP may have only minor difficulty with fine motor skills, such as grasping and manipulating items with their hands. A severe form of CP could involve significant muscle problems in all four limbs, intellectual disabilities (ID), seizures, and difficulties with vision, speech, and hearing.

Muscles that receive abnormal messages from the brain may be constantly contracted and tight (spastic), exhibit involuntary writhing movements (athetosis), or have difficulty with voluntary movement (dyskinesia). There can also be a lack of balance and coordination with unsteady movements (ataxia). A combination of any of these problems may also occur. Spastic CP and mixed CP constitute the majority of cases. Effects on the muscles can range from mild weakness or partial paralysis (*paresis*), to complete loss of voluntary control of a muscle or group of muscles (*plegia*). CP is also designated by the number of limbs affected. For instance, affected muscles in one limb is monoplegia, both arms or both legs is diplegia, both limbs on one side of the body is hemiplegia, and in all four limbs is quadriplegia. Muscles of the trunk, neck, and head may be affected as well.

Risk factors

Babies born prematurely or at low birth weights are at higher risk for cerebral palsy.

Two factors are involved in the risk for CP associated with **prematurity**. First, premature babies are at higher risk for various CP–associated medical complications, such as intracerebral hemorrhage, infection, and difficulty in breathing, to name a few. Second, the onset of **premature labor** may be induced, in part, by complications that have already caused neurologic damage in the fetus. A combination of both factors almost certainly plays a role in some cases of CP. The tendency toward premature delivery tends to run in families, but the genetic mechanisms are far from clear.

An increase in multiple birth pregnancies in recent years, especially in the United States, is blamed on the increased use of fertility drugs. As the number of fetuses in a **pregnancy** increases, the risks for abnormal development and premature delivery also increase. Children from twin pregnancies have four times the risk of developing CP as children from singleton pregnancies, owing to the fact that more twin pregnancies are delivered prematurely. The risk for CP in a child of triplets is up to 18 times greater. Furthermore, recent evidence suggests that a baby from a pregnancy in which its twin died before birth is at increased risk for CP.

Causes and symptoms

CP can be caused by a number of different mechanisms at various times—from several weeks after conception, through birth, to early childhood. For many years, it was accepted that most cases of CP were due to brain injuries received during a traumatic birth, known as birth asphyxia. However, research has shown that only 5–10% of CP can be attributed to birth **trauma**. Causes can be grouped into those that occur during pregnancy (prenatal), those that happen around the time of birth (perinatal), and those that occur after birth (postnatal).

Prenatal causes

Although much has been learned about human embryology in the last couple of decades, a great deal remains unknown. Studying prenatal human development is difficult because the embryo and fetus develop in a closed environment—the mother's womb. However, the relatively recent development of a number of prenatal tests has opened a window on the process. Add to that more accurate and complete evaluations of newborns, especially those with problems, and a clearer picture of what can go wrong before birth is possible.

The complicated process of brain development before birth is susceptible to many chance errors that can result in abnormalities of varying degrees. Some of these errors will result in structural anomalies of the brain, while others may cause undetectable, but significant, abnormalities in how the cerebral cortex is "wired." An abnormality in structure or wiring is sometimes hereditary, but is most often due to chance, or a cause unknown at this time. Whether and how much genetics played a role in a particular brain abnormality depends to some degree on the type of anomaly and the form of CP it causes.

Several maternal–fetal infections are known to increase the risk for CP, including **rubella** (German **measles**, now rare in the United States), cytomegalovirus (CMV), and **toxoplasmosis**. Each of these infections is considered a risk to the fetus only if the mother contracts it for the first time during that pregnancy. Even in those cases, though, most babies will be born normal. Most women are immune to all three infections by the time they reach childbearing age, but a

woman's immune status can be determined using the TORCH (Toxoplasmosis, Rubella, Cytomegalovirus, and Herpes) test before or during pregnancy.

Just as a **stroke** can cause neurologic damage in an adult, so too can this type of event occur in the fetus. A burst blood vessel in the brain followed by uncontrolled bleeding (coagulopathy), known as intracerebral hemorrhage, could cause a fetal stroke, or a cerebral blood vessel could be obstructed by a clot (**embolism**). Infants who later develop CP, along with their mothers, are more likely than other mother–infant pairs to test positive for factors that put them at increased risk for bleeding episodes or **blood clots**. Some **coagulation disorders** are strictly hereditary, but most have a more complicated basis.

A teratogen is any substance to which a woman is exposed that has the potential to harm the embryo or fetus. Links between a drug or other chemical exposure during pregnancy and a risk for CP are difficult to prove. However, any substance that might affect fetal brain development, directly or indirectly, could increase the risk for CP. Furthermore, any substance that increases the risk for premature delivery and low birth weight, such as alcohol, tobacco, or cocaine, among others, might indirectly increase the risk for CP.

The fetus receives all nutrients and oxygen from blood that circulates through the placenta. Therefore, anything that interferes with normal placental function might adversely affect development of the fetus, including the brain, or might increase the risk for premature delivery. Structural abnormalities of the placenta, premature detachment of the placenta from the uterine wall (abruption), and placental infections (chorioamnionitis) are thought to pose some risk for CP.

Certain conditions in the mother during pregnancy might pose a risk to fetal development leading to CP. Women with autoimmune anti–thyroid or anti–phospholipid (APA) antibodies are at slightly increased risk for CP in their children. A potentially important clue uncovered recently points toward high levels of cytokines in the maternal and fetal circulation as a possible risk for CP. Cytokines are proteins associated with inflammation, such as from infection or **autoimmune disorders**, and they may be toxic to neurons in the fetal brain. More research is needed to determine the exact relationship, if any, between high levels of cytokines in pregnancy and CP. A woman has some risk of developing the same complications in more than one pregnancy, slightly increasing the risk for more than one child with CP.

Serious physical trauma to the mother during pregnancy could result in direct trauma to the fetus as well, or injuries to the mother could compromise the availability of nutrients and oxygen to the developing fetal brain.

Perinatal causes

Birth asphyxia significant enough to result in CP is now uncommon in developed countries. Tight nuchal cord (umbilical cord around the baby's neck) and prolapsed cord (cord delivered before the baby) are possible causes of birth asphyxia, as are bleeding and other complications associated with **placental abruption** and **placenta previa** (placenta lying over the cervix).

Infection in the mother is sometimes not passed to the fetus through the placenta, but is transmitted to the baby during delivery. Any such infection that results in serious illness in the newborn has the potential to produce some neurological damage.

Postnatal causes

The remaining 15% of CP is due to neurological injury sustained after birth. CP that has a postnatal cause is sometimes referred to as acquired CP, but this is only accurate for those cases caused by infection or trauma.

Incompatibility between the Rh blood types of mother and child (mother Rh negative, baby Rh positive) can result in severe anemia in the baby (**erythroblastosis fetalis**). This may lead to other complications, including severe **jaundice**, which can cause CP. Rh disease in the newborn is now rare in developed countries due to routine screening of maternal blood type and treatment of pregnancies at risk. The routine, effective treatment of jaundice due to other causes has also made it an infrequent cause of CP in developed countries. Rh blood type poses a risk for recurrence of Rh disease if treatment is not provided.

Serious infections that affect the brain directly, such as **meningitis** and encephalitis, may cause irreversible damage to the brain, leading to CP. A **seizure disorder** early in life may cause CP, or may be the product of a hidden problem that causes CP in addition to seizures. Unexplained (idiopathic) seizures are hereditary in only a small percentage of cases. Although rare in infants born healthy at or near term, intracerebral hemorrhage and brain embolism, like fetal stroke, are sometimes genetic.

Physical trauma to an infant or child resulting in brain injury, such as from **abuse**, accidents, or near drowning/suffocation, might cause CP. Likewise, ingestion of a toxic substance such as lead, mercury, poisons, or certain chemicals could cause neurological

WWW.BOOKBAZ.IR

damage. Accidental overdose of certain medications might also cause similar damage to the central nervous system.

Prematurity and multiple birth pregnancy

Advances in the medical care of premature infants in the last 20 years have dramatically increased the rate of survival of these fragile newborns. However, as gestational age at delivery and birth weight of a baby decrease, the risk for CP dramatically increases. A term pregnancy is delivered at 37–41 weeks gestation. The risk for CP in a preterm infant (32–37 weeks) is increased about five–fold over the risk for an infant born at term. Survivors of extremely preterm births (less than 28 weeks) face as much as a fifty–fold increase in risk. About 50% of all cases of CP now being diagnosed are in children who were born prematurely.

Symptoms

By definition, the defect in cerebral function causing CP is nonprogressive. However, the symptoms of CP often change over time. Most of the symptoms of CP relate in some way to the aberrant control of muscles. To review, CP is categorized first by the type of movement/postural disturbance(s) present, then by a description of which limbs are affected, and finally by the severity of motor impairment. For example, spastic diplegia refers to continuously tight muscles that have no voluntary control in both legs, while athetoid quadraparesis describes uncontrolled writhing movements and muscle weakness in all four limbs. These three-part descriptions are helpful in providing a general picture, but cannot give a complete description of any one person with CP. In addition, the various "forms" of CP do not occur with equal frequency-spastic diplegia is seen in more individuals than is athetoid quadraparesis. CP can also be loosely categorized as mild, moderate, or severe, but these are very subjective terms with no firm boundaries between them.

A muscle that is tensed and contracted is hypertonic, while excessively loose muscles are hypotonic. Spastic, hypertonic muscles can cause serious orthopedic problems, including **scoliosis** (spine curvature), hip dislocation, or **contractures**. A contracture is shortening of a muscle, aided sometimes by a weak-opposing force from a neighboring muscle. Contractures may become permanent, or "fixed," without some sort of intervention. Fixed contractures may cause postural abnormalities in the affected limbs. Clenched fists and contracted feet (equinus or equinovarus) are common in people with CP. Spasticity in the thighs causes them to turn in and cross at the knees, resulting in an unusual method of walking known as a "scissors gait." Any of the joints in the limbs may be stiff (immobilized) due to spasticity of the attached muscles.

Athetosis and dyskinesia often occur with spasticity, but do not often occur alone. The same is true of ataxia. It is important to remember that "mild CP" or "severe CP" refers not only to the number of symptoms present, but also to the level of involvement of any particular class of symptoms.

Mechanisms that can cause CP are not always restricted to motor–control areas of the brain. Other neurologically based symptoms may include:

- ID/learning disabilities
- behavioral disorders
- seizure disorders
- visual impairment
- hearing loss
- speech impairment (dysarthria)
- abnormal sensation and perception

These problems may have a greater impact on a child's life than the physical impairments of CP, although not all children with CP are affected by other problems. Many infants and children with CP have growth impairment. About one-third of individuals with CP have moderate-to-severe ID, one-third have mild ID, and one-third have normal intelligence.

Diagnosis

Examination

Diagnosing CP in an infant is often a difficult and slow process that takes time to establish with certainty, as there are other health problems that can mimic the condition. The physician may suspect that the infant has CP because of a history of difficulties at birth, seizures, feeding problems, or low muscle tone. Detailed medical and developmental history, including the history of the pregnancy and delivery, medications taken by the mother during fetal development, infections, and fetal movement are all considered. A detailed family history, including the mother's history of **miscarriage**, relatives with similar conditions, ethnic background, and consanguinity (marriage between close blood relatives) can also prove helpful.

The signs of CP are not usually noticeable at birth. Children normally progress through a predictable set of developmental milestones through the first 18 months of life. Children with CP, however, tend to develop these skills more slowly because of their motor impairments, and delays in reaching milestones are

KEY TERMS

Asphyxia—Lack of oxygen. In the case of cerebral palsy, lack of oxygen to the brain.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Athetosis—A condition marked by slow, writhing, involuntary muscle movements.

Cerebral palsy—Movement disability resulting from nonprogressive brain damage.

Coagulopathy—A disorder in which blood is either too slow or too quick to coagulate (clot).

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Cytokine—A protein associated with inflammation that, at high levels, may be toxic to nerve cells in the developing brain.

Diplegia—Paralysis affecting like parts on both sides the body, such as both arms or both legs.

Dorsal rhizotomy—A surgical procedure that cuts nerve roots to reduce spasticity in affected muscles.

Dyskinesia—Impaired ability to make voluntary movements.

Hemiplegia—Paralysis of one side of the body.

Hypotonia—Reduced or diminished muscle tone.

Quadriplegia—Paralysis of all four limbs.

Serial casting—A series of casts designed to gradually move a limb into a more functional position.

Spastic—A condition in which the muscles are rigid, posture may be abnormal, and fine motor control is impaired.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

Static encephalopathy—A disease of the brain that does not get better or worse.

Tenotomy—A surgical procedure that cuts the tendon of a contracted muscle to allow lengthening.

usually the first symptoms of CP. Babies with more severe cases of CP are normally diagnosed earlier than others.

Selected developmental milestones, and the ages for normally acquiring them, are given in the following list. If a child does not acquire the skill by the age shown in parentheses, there is some cause for concern.

- Sits well unsupported—6 months (8–10 months)
- Babbles—6 months (8 months)
- Crawls—9 months (12 months)
- Finger feeds, holds bottle—9 months (12 months)
- Walks alone—12 months (15–18 months)
- Uses one or two words other than dada/mama—12 months (15 months)
- Walks up and down steps—24 months (24–36 months)
- Turns pages in books; removes shoes and socks—24 months (30 months)

Children do not consistently favor one hand over the other before 12–18 months, and doing so may be a sign that the child has difficulty using the other hand. This same preference for one side of the body may show up as asymmetric crawling or, later on, favoring one leg while climbing stairs.

It must be remembered that children normally progress at somewhat different rates, and slow beginning accomplishment is often followed by normal development. Other causes for developmental delay—some benign, some serious—should be excluded before considering CP as the answer. CP is nonprogressive, so continued loss of previously acquired milestones indicates that CP is not the cause of the problem.

Tests

No one test is diagnostic for CP, but certain factors increase suspicion. The Apgar score measures a baby's condition immediately after birth. Babies that have low Apgar scores are at increased risk for CP. Presence of abnormal muscle tone or movements may indicate CP, as may the persistence of infantile reflexes. Imaging of the brain using **ultrasound**, x rays, MRI, and/or CT scans may reveal a structural anomaly. Some brain lesions associated with CP include scarring, cysts, expansion of the cerebral ventricles (**hydrocephalus**), periventricular leukomalacia (an abnormality of the area surrounding the ventricles), areas of dead tissue (**necrosis**), and evidence of an intracerebral hemorrhage or blood clot. Ultrasound in the neonate (newborn) is also used as it provides information about the structures of the brain as well as diagnostic information on possible hemorrhage or hypoxic–ischemic (lack of

WWW.BOOKBAZ.IR

oxygen) injury. Blood and urine biochemical tests, as well as genetic tests, may be used to rule out other possible causes, including muscle and peripheral nerve diseases, mitochondrial and metabolic diseases, and other inherited disorders. Evaluations by a pediatric developmental specialist and a geneticist may be of benefit.

Treatment

Cerebral palsy cannot be cured, but many of the disabilities it causes can be managed through planning and timely care. Treatment for a child with CP depends on the severity, nature, and location of the primary muscular symptoms, as well as any associated problems that might be present. Optimal care of a child with mild CP may involve regular interaction with only a physical therapist and occupational therapist, whereas care for a more severely affected child may include visits to multiple medical specialists throughout life. With proper treatment and an effective plan, most people with CP can lead productive, happy lives.

Parents of a child newly diagnosed with CP are not likely to have the necessary expertise to coordinate the full range of care their child will need. Although knowledgeable and caring medical professionals are indispensable for developing a care plan, a potentially more important source of information and advice is other parents who have dealt with the same set of difficulties. Support groups for parents of children with CP can be significant sources of both practical advice and emotional support. Many cities have support groups that can be located through the United Cerebral Palsy Association, and most large medical centers have special multidisciplinary clinics for children with developmental disorders.

Spasticity, muscle weakness, coordination, ataxia, and scoliosis are all significant impairments that affect the posture and mobility of a person with CP. Physical and occupational therapists work with the patient and the family to maximize the ability to move affected limbs, develop normal motor patterns, and maintain posture. Assistive technology such as wheelchairs, walkers, shoe inserts, crutches, and braces are often required. A speech therapist and high–tech aids, such as computer–controlled communication devices, can make a tremendous difference in the life of those who have speech impairments.

Daily range of motion (ROM) exercises are important to prevent or delay contractures (fixed, rigid muscles) secondary to spasticity, and to maintain mobility of joints and soft tissues. Stretching exercises are performed to increase motion. Progressive resistance exercises also increase strength. Age–appropriate play and adaptive toys and games using the desired exercises are important to elicit the child's full cooperation. Strengthening knee extensor muscles helps to improve crouching and stride length. Postural and motor control training is important following the normal developmental sequence of children (i.e., achieve head and neck control if possible before advancing to trunk control).

Occupational therapists keep the child's developmental age in mind and use adaptive equipment as needed to help attain these milestones. For example, if a child is developmentally ready to stand and explore the environment, but is limited by lack of motor control, a stander or modified walker is used. Performance based upon previous success is encouraged to maintain the child's interest and cooperation. Assistive devices and durable medical equipment help attain function that may not be possible otherwise. Orthotic devices frequently are required to maintain functional joint position especially in persons who are non–ambulatory. Frequent reevaluation of orthotic devices is important as children quickly outgrow them and can develop skin irritation from improper use of orthotic devices.

Recreational therapy, especially hippotherapy (horseback riding therapy) is frequently a well–liked activity of parents and patients alike to help with muscle tone, range of motion, strength, coordination, and balance. Hippotherapy also offers many potential cognitive, physical, and emotional benefits. Incorporation of play into all of a child's therapies is important. The child should view physical and **occupational therapy** as fun, not work. Caregivers should seek fun and creative ways to stimulate children, especially those who have decreased ability to explore their own environments.

Drugs

Before fixed contractures develop, muscle–relaxant drugs such as diazepam (Valium), dantrolene (Dantrium), and baclofen (Lioresal) may be prescribed. Botulinum toxin (Botox), a newer and highly effective treatment, is injected directly into the affected muscles. Alcohol or phenol injections into the nerve controlling the muscle are another option. Multiple medications are available to control seizures, and athetosis can be treated using medications such as trihexyphenidyl HCl (Artane) and benztropine (Cogentin).

Alternatives

Fixed contractures are usually treated with either serial casting or surgery. The most commonly used surgical procedures are tenotomy, tendon transfer, and dorsal rhizotomy. In tenotomy, tendons of the affected muscle are cut and the limb is cast in a more normal position while the tendon regrows. Alternatively, tendon transfer involves cutting and reattaching a tendon at a different point on the bone to enhance the length and function of the muscle. A neurosurgeon performing dorsal rhizotomy carefully cuts selected nerve roots in the spinal cord to prevent them from stimulating the spastic muscles. Neurosurgical techniques in the brain such as implanting tiny electrodes directly into the cerebellum, or cutting a portion of the hypothalamus, have very specific uses and have had mixed results.

Clinical trials

Many clinical trials for the treatment of cerebral palsy are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2009, NIH reported 53 on-going or recently completed studies.

A few examples include:

- The evaluation of the effectiveness of hyperbaric oxygen treatments and the potential longer term effects in children between the ages of three and eight years with spastic CP. (NCT00290186)
- The classification of types of hypertonia in patients with cerebral palsy. (NCT00123708)
- A study of the radiographic and clinical outcomes of scoliosis surgical treatment in patients with CP. (NCT00680264)
- A study on how the muscle architecture of the quadriceps muscles in CP adapts to two separate training programs. (NCT00629070)
- The effectiveness of acupuncture as complementary therapy for CP. (NCT00221247)
- The effects of botulinum toxin injections on walking and on the changes it causes in the muscle, brain and spinal cord of CP patients. (NCT00503620)
- The assessment of the predictive value of generalized movements in preterm and term infants who are at risk for development of cerebral palsy. (NCT00749008)

Clinical trial information is constantly updated by NIH and the most recent information on CP trials can be found at: http://clinicaltrials.gov.

Prognosis

The prognosis of persons with CP varies according to the severity of the disorder. Some children have only mild problems in muscle tone and no problems with daily activities, while others are unable to purposefully move any part of the body. Regression, or worsening of long-term symptoms, is not characteristic of CP. If regression occurs, it is necessary to look for a different cause of the child's problems. In order for a child to be able to walk, a major cascade of events in motor control have to occur. A child must be able to hold up his head before he can sit up on his own, and he must be able to sit independently before he can walk on his own. It is generally assumed that if a child is not sitting up by himself by age four or walking by age eight, he will never be an independent walker. But a child who starts to walk at age three will certainly continue to walk unless he has a disorder other than CP.

In people with severe CP, motor problems often lead to medical complications, including more frequent and serious infections, severe breathing problems, feeding intolerance, and skin breakdown. These medical complications can lead to frequent hospitalizations and a shortened life expectancy. **Epilepsy** also occurs in about a third of children with CP and is more frequent in patients with spastic quadriplegia or ID. Cognitive impairment occurs more frequently in CP than in the general population, and mental delays or some form of learning disability has been estimated to occur in over two thirds of CP cases.

Prevention

Research in the early 2000s is focused on the possible benefits of recognizing and treating coagulopathies and inflammatory disorders in the prenatal and perinatal periods in order to reduce the incidence of CP and other congenital diseases. The use of magnesium sulfate in pregnant women with **preeclampsia** or threatened preterm delivery may reduce the risk of CP in very preterm infants. Finally, the risk of CP can be decreased through good maternal **nutrition**, avoidance of drugs and alcohol during pregnancy, and prevention or prompt treatment of infections.

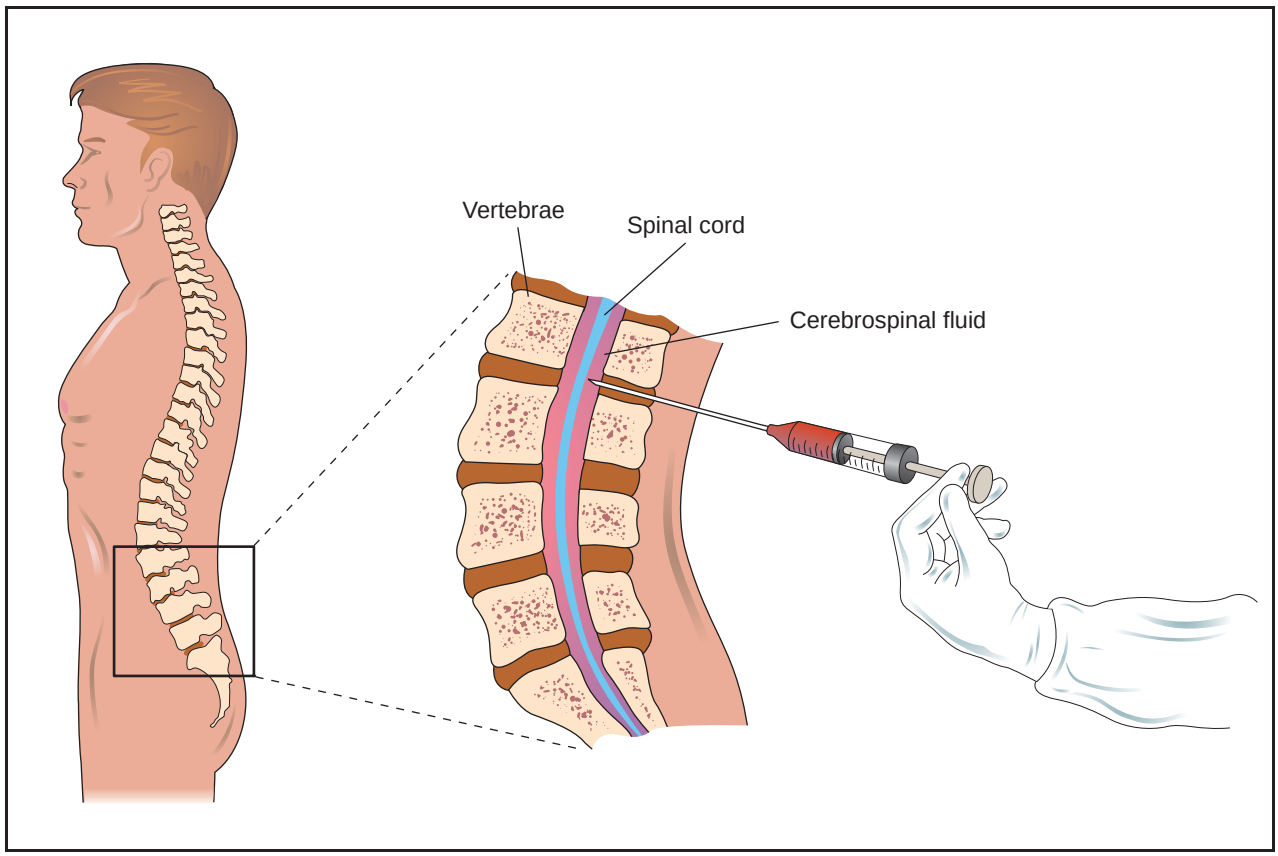
Cerebrospinal fluid (CSF) analysis

Definition

Cerebrospinal fluid (CSF) analysis is a set of laboratory tests that examine a sample of the fluid surrounding the brain and spinal cord. This fluid is an ultrafiltrate of plasma. It is clear and colorless. It contains glucose, electrolytes, amino acids, and other small molecules found in plasma, but has very little protein and few cells. CSF protects the central nervous



During a lumbar puncture, or spinal tap, a procedure in which cerebrospinal fluid is aspirated, the physician inserts a hollow, thin needle in the space between two vertebrae of the lower back and slowly advances it toward the spine. The cerebrospinal fluid pressure is then measured and the fluid is withdrawn for laboratory analysis. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

system from injury, cushions it from the surrounding bone structure, provides it with nutrients, and removes waste products by returning them to the blood. CSF is withdrawn from the subarachnoid space through a needle in a procedure called a **lumbar puncture** or spinal tap. CSF analysis includes tests in clinical chemistry, hematology, immunology, and **microbiology**. Usually three or four tubes are collected. The first tube is used for chemical and/or serological analysis, and the last two tubes are used for hematology and microbiology tests. This reduces the chances of a falsely elevated white cell count caused by a traumatic tap (bleeding into the subarachnoid space at the puncture site), and contamination of the bacterial culture by skin germs or flora.

Purpose

The purpose of a CSF analysis is to diagnose medical disorders that affect the central nervous system. The CSF analysis may also be used to measure the pressure in the spinal fluid. Some of the conditions that may be diagnosed with the analysis are:

- meningitis and encephalitis, which may be viral, bacterial, fungal, or parasitic infections
- metastatic tumors (e.g., leukemia) and central nervous system tumors that shed cells into the CSF
- syphilis, a sexually transmitted bacterial disease
- bleeding (hemorrhaging) in the brain and spinal cord
- multiple sclerosis, a degenerative nerve disease that results in the loss of the myelin coating of the nerve fibers of the brain and spinal cord
- Guillain-Barré syndrome, a demyelinating disease involving peripheral sensory and motor nerves

Description

Lumbar puncture, also known as a spinal tap, is performed by inserting the needle between the fourth and fifth lumbar vertebrae (L4-L5). This location is used because the spinal cord stops near L2, and a

WWW.BOOKBAZ.IR

needle introduced below this level will miss the cord. In rare instances, such as a spinal fluid blockage in the middle of the back, a physician may perform a spinal tap in the cervical spine.

Other methods of CSF collection

A Cisternal puncture may also be used to collect CSF samples. During a Cisternal puncture procedure, a needle is placed below the occipital bone, which is located at the back of the skull. This procedure is performed with the use of fluoroscopy. This has high risks due to the needle insertion being close to the brain stem.

Ventricular puncture is another method that may be used to collect CSF for analysis. This procedure is commonly performed in the operating room. The patient is under a general anesthetic and a hole is drilled in the skull. A needle is inserted directly into one of the brain's ventricles. This technique is rarely used due to the severity of the procedure. It is used for patients with possible brain herniation.

CSF fluid samples may also be collected by other means, such as during the insertion of a **ventricular shunt**. CSF samples can be collected using a shunt or ventricular drain that is already in place.

Measurements

Routine examination of CSF includes visual observation of color and clarity and tests for glucose, protein, lactate, lactate dehydrogenase, red blood cell count, **white blood cell count** with differential, **syphilis** serology (testing for antibodies indicative of syphilis), Gram stain, and bacterial culture. Further tests may need to be performed depending upon the results of initial tests and the presumptive diagnosis. For example, an abnormally high total protein seen in a patient suspected of having a demyelinating disease, such as **multiple sclerosis**, dictates CSF **protein electrophoresis** and measurement of immunoglobulin levels and myelin basic protein.

GROSS EXAMINATION. Color and clarity are important diagnostic characteristics of CSF. Straw, pink, yellow, or amber pigments (xanthochromia) are abnormal and indicate the presence of bilirubin, hemoglobin, red blood cells, or increased protein. Turbidity (suspended particles) indicates an increased number of cells. Gross examination is an important aid to differentiating a **subarachnoid hemorrhage** from a traumatic tap. The latter is often associated with sequential clearing of CSF as it is collected, streaks of blood in an otherwise clear fluid, or a sample that clots.

GLUCOSE. CSF glucose is normally approximately two-thirds of the fasting plasma glucose. A glucose level below 40 milligrams per deciliter (mg/dL) is significant and occurs in bacterial and fungal **meningitis** and in malignancy. Increased CSF glucose is a sign of high blood sugar.

PROTEIN. Total protein levels in CSF are normally very low—albumin makes up approximately two-thirds of the total. High levels are seen in many conditions including bacterial and fungal meningitis, multiple sclerosis, tumors, subarachnoid hemorrhage, and traumatic tap. Decreased protein is a sign of rapid CSF production.

LACTATE. The CSF lactate is used mainly to help differentiate bacterial and fungal meningitis, which cause increased lactate, from viral meningitis, which does not.

LACTATE DEHYDROGENASE. This enzyme is elevated in bacterial and fungal meningitis, malignancy, and subarachnoid hemorrhage.

WHITE BLOOD CELL (WBC) COUNT. The number of white blood cells in CSF is very low, usually necessitating a manual WBC count. An increase in WBCs may occur in many conditions including infection (viral, bacterial, fungal, and parasitic), allergy, leukemia, multiple sclerosis, hemorrhage, traumatic tap, encephalitis, and Guillain-Barré syndrome. The WBC differential helps to distinguish many of these causes. For example, viral infection is usually associated with an increase in lymphocytes, while bacterial and **fungal infections** are associated with an increase in polymorphonuclear leukocytes (neutrophils). The differential may also reveal eosinophils associated with allergy and ventricular shunts; macrophages with ingested bacteria (indicating meningitis), RBCs (indicating hemorrhage), or lipids (indicating possible cerebral infarction); blasts (immature cells) that indicate leukemia; and malignant cells characteristic of the tissue of origin. About 50% of metastatic cancers that infiltrate the central nervous system and about 10% of central nervous system tumors will shed cells into the CSF.

RED BLOOD CELL (RBC) COUNT. While not normally found in CSF, RBCs will appear whenever bleeding has occurred. Red cells in CSF signal subarachnoid hemorrhage, **stroke**, or traumatic tap. Since white cells may enter the CSF in response to local infection, inflammation, or bleeding, the RBC count is used to correct the WBC count so that it reflects conditions other than hemorrhage or a traumatic tap. This is accomplished by counting RBCs and WBCs in both blood and CSF. The ratio of RBCs in CSF to blood is multiplied by the blood WBC count. This value is subtracted from the CSF WBC count to eliminate WBCs derived from hemorrhage or traumatic tap.

KEY TERMS

Demyelination—The loss of myelin with preservation of the axons or fiber tracts. Central demyelination occurs within the central nervous system, and peripheral demyelination affects the peripheral nervous system as with Guillain-Barré syndrome.

Encephalitis—An inflammation or infection of the brain and spinal cord caused by a virus or as a complication of another infection.

Fluoroscopy—A diagnostic imaging procedure that uses x rays and contrast agents to visualize internal structures in real time.

Guillain-Barré syndrome—A demyelinating disease involving nerves that affect the extremities and causing weakness and motor and sensory dysfunction.

Meningitis—An infection of the membranes that cover the brain and spinal cord.

Multiple sclerosis—A disease that destroys the covering (myelin sheath) of nerve fibers of the brain and spinal cord.

Spinal canal—The cavity or hollow space within the spine that contains the spinal cord and the cerebrospinal fluid.

Subarachnoid—The space underneath the arachnoid membrane, a thin membrane enclosing the brain and spinal cord.

Treponeme—A term used to refer to any member of the genus *Treponema*, which is an anaerobic bacteria consisting of cells, 3–8 μm in length, with acute, regular, or irregular spirals and no obvious protoplasmic structure.

Ventricular drain—Used to measure the pressure inside the head or to relieve a blockage of the flow of the CSF.

Ventricular shunt—A tube that is placed in one of the fluid filled chambers inside the brain (ventricles) to drain excess fluid and relieve pressure.

Vertebrae—The bones of the spinal column. There are 33 along the spine, with five (called L1-L5) making up the lower lumbar region.

GRAM STAIN. The Gram stain is performed on a sediment of the CSF and is positive in at least 60% of cases of bacterial meningitis. Culture is performed for both aerobic and anaerobic bacteria. In addition, other stains, such as the acid-fast stain for *Mycobacterium tuberculosis*, fungal culture, and rapid identification tests (tests for bacterial and fungal antigens), may be performed routinely.

SYPHILIS SEROLOGY. This serology involves testing for antibodies that indicate neurosyphilis. The fluorescent treponemal antibody-absorption (FTA-ABS) test is often used and is positive in persons with active and treated syphilis. The test is used in conjunction with the VDRL test for nontreponemal antibodies, which is positive in most persons with active syphilis, but negative in treated cases.

CSF PRESSURE. Increased intracranial pressure is pressure within the skull and can be due to increased CSF. Decreased CSF pressure may be due to a spinal cord tumor, **fainting**, **shock**, or diabetic **coma**.

Precautions

In some circumstances, a lumbar puncture to withdraw a small amount of CSF for analysis may lead to serious complications. Lumbar punctures should be performed only with extreme caution, and only if the benefits are thought to outweigh the risks. In people who have bleeding disorders, lumbar puncture can cause hemorrhage that can compress the spinal cord. If there is increased spinal column pressure, as may occur with a **brain tumor** and other conditions, removal of CSF can cause the brain to herniate, compressing the brain stem and other vital structures and leading to irreversible brain damage or death. Bacteria introduced during the puncture may cause meningitis. For this reason, aseptic technique must be followed strictly, and a lumbar puncture should never be performed at the site of a localized skin lesion.

Specimens should be handled with caution to avoid contamination with skin flora. They should be refrigerated if analysis cannot be performed immediately.

Aftercare

After the procedure, the site of the puncture is covered with a sterile bandage. The patient should remain lying down for four to six hours after the lumbar puncture. Vital signs should be monitored every 15 minutes for four hours, then every 30 minutes for another four hours. The puncture site should be observed for signs of weeping or swelling for 24 hours. The neurological status of the patient should also be

WWW.BOOKBAZ.IR

evaluated for such symptoms as numbness and/or tingling in the lower extremities.

Results

Normal results for various values include:

- Gross appearance: normal CSF is clear and colorless
- CSF opening pressure: 50–175 millimeters (mm) H_2O
- Specific gravity: 1.006–1.009
- Glucose: 40–80 mg/dL
- Total protein: 15–45 mg/dL
- LD: 1/10 of serum level
- Lactate: less than 35 mg/dL
- Leukocytes (white blood cells): 0–5/microL (adults and children); up to 30/microL (newborns)
- Differential: 60–80% lymphocytes; up to 30% monocytes and macrophages (somewhat higher in neonates); other cells 2% or less
- Gram stain: negative
- Culture: sterile
- Syphilis serology: negative
- Red blood cell count: there should be no red blood cells in the CSF unless the needle passes through a blood vessel

Risks

The most common side effect after the removal of CSF is a **headache**. This occurs in 10–30% of adult patients and in up to 40% of children. It is caused by a decreased CSF pressure related to a small leak of CSF through the puncture site. These headaches usually are a dull **pain**, although some people report a throbbing sensation. A stiff neck and nausea may accompany the headache. Lumbar puncture headaches typically begin within two days after the procedure and persist from a few days to several weeks or months. Other risks might include discomfort during the procedure, hypersensitivity to the anesthetic medication, or infection at the needle insertion site.

Cerumen impaction

Definition

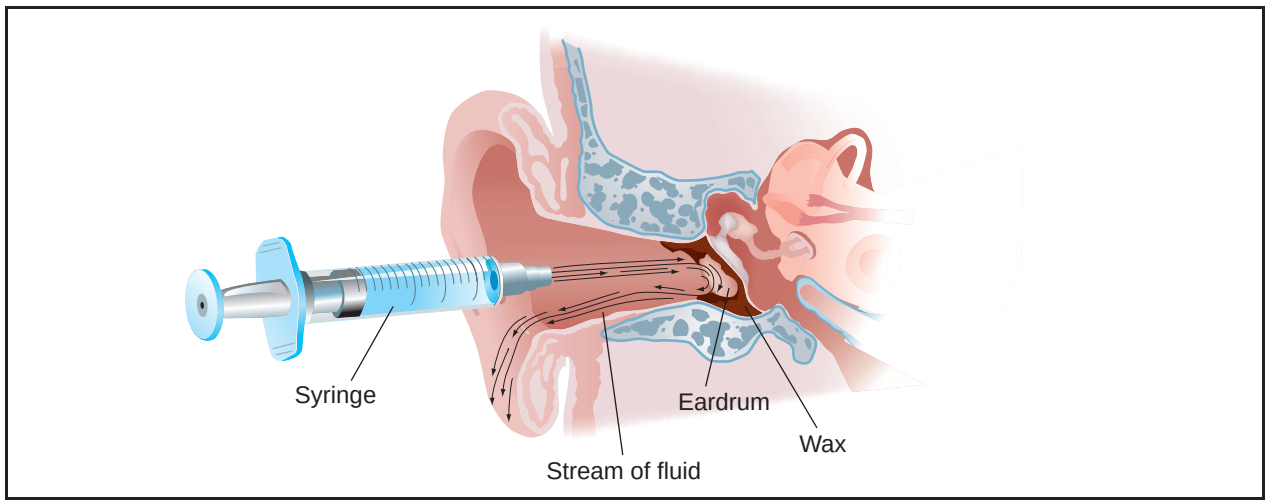
Cerumen impaction is a condition in which earwax has become tightly packed in the external ear canal to the point that the canal is blocked.

Description

Cerumen impaction develops when earwax accumulates in the inner part of the ear canal and blocks the eardrum. It affects between 2% and 6% of the general population in the United States. Impaction does not happen under normal circumstances because cerumen is produced by glands in the outer part of the ear canal; it is not produced in the inner part. The cerumen traps sand or dust particles before they reach the ear drum. It also protects the outer part of the ear canal because it repels water. The slow movement of the outer layer of skin of the ear canal carries cerumen toward the outer opening of the ear. As the older cerumen reaches the opening of the ear, it dries out and falls away.

Causes and symptoms

Cerumen is most likely to become impacted when it is pushed against the eardrum by cotton-tipped applicators, hair pins, or other objects that people put in their ears; and when it is trapped against the eardrum by a hearing aid. Less common causes of



Ear wax is removed by flushing the ear canal with warm fluid. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

cerumen impaction include overproduction of earwax by the glands in the ear canal, or an abnormally shaped ear canal.

The most important symptom of cerumen impaction is partial loss of hearing. Other symptoms are **itching**, **tinnitus** (noise or ringing in the ears), a sensation of fullness in the ear, and **pain**.

Diagnosis

The diagnosis of impacted cerumen is usually made by examining the ear canal and eardrum with an otoscope, an instrument with a light attached that allows the doctor to look into the canal.

Treatment

Irrigation is the most common method of removing impacted cerumen. It involves washing out the ear canal with water from a commercial irrigator or a syringe with a catheter attached. Although some doctors use Water Piks to remove cerumen, most do not recommend them because the stream of water is too forceful and may damage the eardrum. The doctor may add a small amount of alcohol, hydrogen peroxide, or other antiseptic. The water must be close to body temperature; if it is too cold or too warm, the patient may feel dizzy or nauseated. After the ear has been irrigated, the doctor will apply antibiotic ear drops to protect the ear from infection.

Irrigation should not be used to remove cerumen if the patient's eardrum is ruptured or missing; if the patient has a history of chronic **otitis media** (inflammation of the middle ear) or a myringotomy (cutting the eardrum to allow fluid to escape from the middle ear); or if the patient has hearing in only one ear.

If irrigation cannot be used or fails to remove the cerumen, the patient is referred to an ear, nose, and throat (ENT) specialist. The specialist can remove the wax with a vacuum device or a curette, which is a small scoop-shaped surgical instrument.

Some doctors prescribe special ear drops, such as Cerumenex, to soften the wax. The most common side effect of Cerumenex is an allergic skin reaction. Over-the-counter wax removal products include Debrox or Murine Ear Drops. A 3% solution of hydrogen peroxide may also be used. These products are less likely to irritate the skin of the ear.

Alternatives

One alternative method that is sometimes touted as a way to remove impacted cerumen is ear candling. Ear candling involves the insertion of a burning candle or a cone of wax-soaked linen or cotton into the affected ear. The person lies on his or her side with the affected ear uppermost. A collecting plate is placed on the ear to catch melted wax. The cone or candle is threaded through a hole in the plate into the ear canal and lit. A variation on this technique involves blowing herbal smoke into the ear through homemade pottery cones. Practitioners of ear candling claim that the heat from the burning candle or smoke creates a vacuum that draws out the impacted cerumen. Some also claim that ear candling improves hearing, relieves sinus infections, cures earache or swimmer's ear, stops tinnitus, or purifies the mind. None of these claims are true. Ear

WWW.BOOKBAZ.IR

KEY TERMS

Cerumen—The medical term for earwax.

Curette—A small scoop-shaped surgical instrument that can be used to remove cerumen if irrigation does not work or cannot be used.

Ear candling—An alternative method for removing impacted cerumen with a lighted hollow cone of paraffin or beeswax. It does not work, and is not considered an acceptable treatment for any ear problem or disorder.

Impaction—A condition in which earwax has become tightly packed in the outer ear to the point that the external ear canal is blocked.

Irrigation—The technique of removing cerumen from the ear canal by flushing it with water.

Myringotomy—Surgical cutting of the ear drum to allow fluid to escape from the middle ear.

Otitis media—Inflammation of the middle ear. Patients who have had recurrent otitis media should not have cerumen removed by irrigation.

Tinnitus—A sensation of noise or ringing in the ears. Tinnitus may be a symptom of cerumen impaction.

candling is not recognized as an acceptable alternative practice by naturopaths, homeopaths, practitioners of Native American medicine, or any other authority on complementary and alternative medicine.

Ear candling is not only an ineffective way to remove impacted cerumen, it can actually damage the ear. According to a 1996 survey of 122 otolaryngologists (doctors who specialize in treating ear, nose, and throat disorders) in the Spokane area, the doctors reported 21 severe ear injuries resulting from ear candling, including 13 cases of external **burns**, seven cases of ear canal obstruction from melted candle wax, and one case of eardrum perforation. Ear candles cannot legally be sold as health devices in the United States because they do not have Food and Drug Administration (FDA) approval. A similar ban is in effect in Canada. Ear candles are, however, available over the Internet and in some health food stores with the labeling "for entertainment only."

Prognosis

In most cases, impacted cerumen is successfully removed by irrigation with no lasting side effects. Irrigation can, however, lead to infection of the outer or the middle ear if the patient has a damaged or absent ear drum. Patients who try to remove earwax themselves with hair pins or similar objects run the risk of perforating the ear drum or damaging the fragile skin covering the ear canal, causing bleeding and the risk of infection.

Prevention

The best method of cleaning the external ear is to wipe the outer opening with a damp washcloth folded over the index finger, without going into the ear canal itself. Two techniques have been recommended to prevent cerumen from reaccumulating in the ear. The patient may place two or three drops of mineral oil into each ear once a week, allow it to remain for two or three minutes, and rinse it out with warm water; or place two drops of Domeboro otic solution in each ear once a week after showering.

Patients who wear **hearing aids** should have their ears examined periodically for signs of cerumen accumulation.

Cervical biopsy *see* **Cervical conization**

Cervical cancer

Definition

Cervical cancer is a disease of the female reproductive system in which the cells lining the cervix (the area between the uterus body and vagina) become abnormal, start to grow uncontrollably, and form invasive tumors. Caught in its early stages, cervical cancer is highly curable; left untreated it can be fatal.

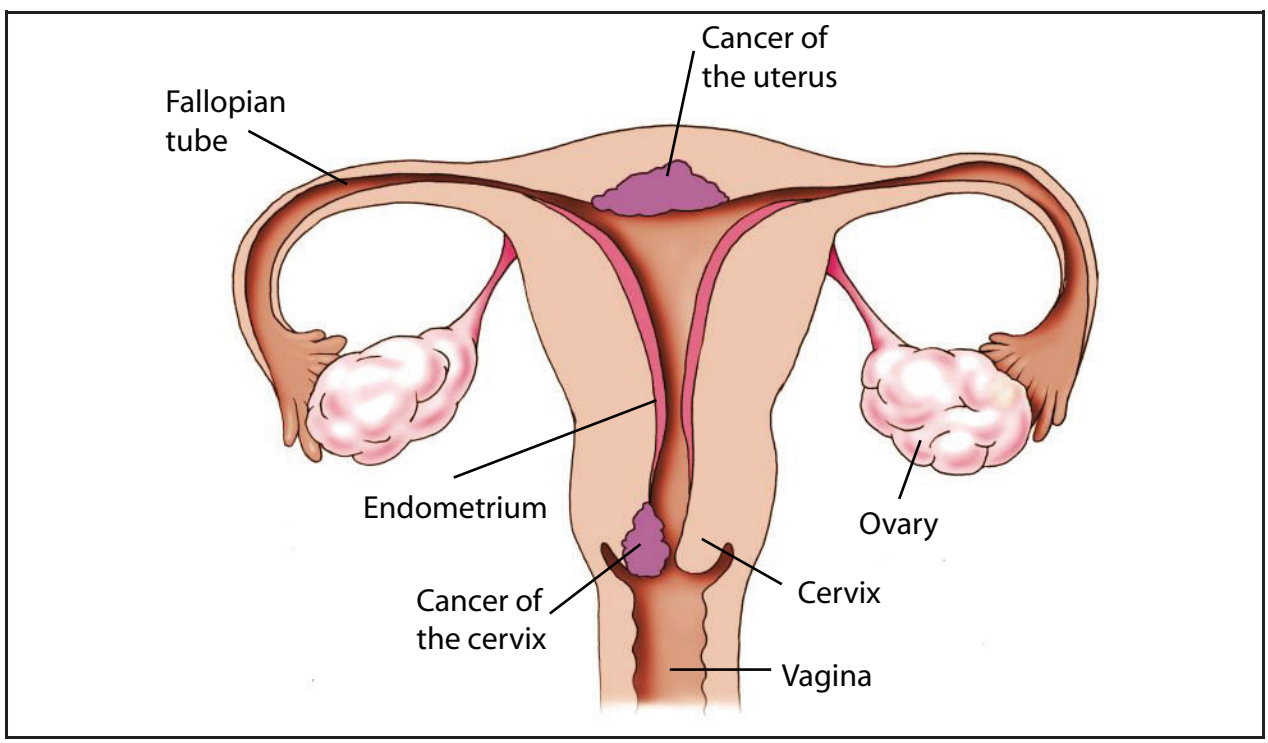
Demographics

In 2009, the American Cancer Society projected that about 11,270 new cases of invasive cervical cancer would be diagnosed in the United States, and about 4,700 American women would die from the disease. Although the median age for diagnosis of cervical cancer in the United States between 2000 and 2004 was 48, almost half of new cases of serious cervical cancer and deaths from cervical cancer are in women aged 65 and older. Rarely is cervical cancer diagnosed in women under age 20. In the United States poor and minority women have the highest rates of cervical cancer and cervical cancer deaths, most likely because they have less access to screening tests and healthcare.

Internationally, about half a million new cases of cervical cancer are diagnosed each year, at least three–quarters of which are in developing countries. In the developing world, cervical cancer is the second most common cancer in women and the third most common cause of cancer death, with nearly 300,000 women dying annually.

Description

There are two types of cervical cancers. They are named after type of cell that becomes cancerous.



Illustrated anatomy of the female reproductive system showing cervical and uterine cancers. *(Illustration by Frank Forney. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

Between 80% and 90% of cervical cancers are squamous cell carcinomas. Squamous cells are thin, flat cells of the surfaces of the skin, the cervix, and linings of various organs. Squamous cell carcinoma originates in the squamous cells on the surface of the ectocervix, the part of the cervix that is next to the vagina. Most of the remaining 10–20% of cervical cancers are adenocarcinomas. This cancer originates in the mucus-producing cells of the inner cervix, or endocervix, the part of the cervix nearest the body of the uterus. Occasionally, cervical cancer may have characteristics of both types of carcinomas. This condition is called adenosquamous carcinoma or mixed carcinoma. In the United States adenocarcinomas have become increasingly common since the 1980s.

Cervical cancer usually is slow to develop. The initial abnormalities that occur in some cervical cells are not cancerous, and not every woman who has abnormal cervical cells develops cancer. The precancerous cells form a lesion called dysplasia. Dysplasia is a common condition, and the abnormal cells often disappear without treatment. Moderate to severe dysplasia may be called carcinoma in situ or non invasive cervical cancer.

In some women, precancerous cells continue to change and become cancerous. This process often takes years, although it occasionally can happen within one year. When the abnormal cells become malignant (cancerous), they start to grow uncontrollably and invade the deeper layers of the cervix, becoming an invasive cervical cancer. Non invasive cervical cancer is about four times more common than invasive cervical cancer.

Screening for cervical cancer is done with a **Pap test** or smear, in which cells are scraped from the cervix and examined for abnormalities under a microscope. In the United States and other developed countries, the rate of cervical cancer has declined steadily since the mid-1950s with widespread use of routine Pap tests. Because cervical cancer develops slowly, early detection makes cervical cancer highly treatable.

Risk factors

Risk factors for cervical cancer include:

- sexual intercourse before age 16
- numerous sexual partners
- sexual partners who have had many sexual partners
- giving birth to seven or more children
- smoking cigarettes
- a weakened immune system.

Diethylstilbestrol (DES), which was given to pregnant women in the United States between 1940 and 1971, may increase the risk of a rare type of cervical cancer in women who were exposed to the drug before birth.

Causes and symptoms

Infection with the human papilloma viruses (HPVs) is associated with about 90% of all cervical cancers. However, HPV infection is very common and only a small number of women with untreated HPV develop cervical cancer. There are more than 80 types of HPV. About 30 of these types can be transmitted sexually, including those that cause **genital warts** (papillomas). About half of sexually transmitted HPVs are associated with cervical cancer. These high-risk HPVs produce a protein that may cause cervical epithelial cells to grow uncontrollably. The virus also makes a second protein that interferes with tumor (cell growth) suppressors that are produced by the human immune system. HPV–16 or HPV–18 are associated with about 90% of invasive cervical cancers.

Although cervical cancer often has no signs or symptoms, possible signs and symptoms include:

- menstrual bleeding that is unusually prolonged or heavy
- vaginal bleeding between periods or after sexual intercourse, douching, or a pelvic exam
- bleeding after menopause
- painful sexual intercourse
- pelvic pain.

Diagnosis

Pap test

Most often, cervical cancer is first detected with a Pap test that is performed as part of a regular pelvic examination. The vagina is spread with a metal or plastic instrument called a speculum. A swab is used to remove mucus and cells from the cervix. This sample is sent to a laboratory for microscopic examination.

The Pap test is a screening tool rather than a diagnostic tool. It is very efficient at detecting cervical abnormalities. The Bethesda System commonly is used to report Pap test results. A negative test means that no abnormalities are present in the cervical tissue. A positive Pap test describes abnormal cervical cells as low-grade or high-grade squamous intraepithelial lesions (SILs), depending on the extent of dysplasia. About 5–10% of Pap tests show at least mild abnormalities. However, a number of factors other than cervical cancer can cause abnormalities, including

KEY TERMS

Adenocarcinoma—Cervical cancer that originates in the mucus–producing cells of the inner or endocervix.

Biopsy—Removal of a small sample of tissue for examination under a microscope; used for the diagnosis and treatment of cervical cancer and precancerous conditions.

Carcinoma in situ—Cancer that is confined to the cells in which it originated and has not spread to other tissues.

Cervix—The narrow, lower end of the uterus forming the opening to the vagina.

Colposcopy—Diagnostic procedure using a hollow, lighted tube (colposcope) to look inside the cervix and uterus.

Conization—Cone biopsy; removal of a cone-shaped section of tissue from the cervix for diagnosis or treatment.

Dysplasia—Abnormal cellular changes that may become cancerous.

Endocervical curettage—Biopsy performed with a curette to scrape the mucous membrane of the cervical canal.

Human papilloma virus (HPV)—A group of viruses that cause abnormal cell growth (warts or papillomas); some types can cause cervical cancer.

Hysterectomy—Removal of the uterus.

Interferon—Potent immune-defense protein produced by viral-infected cells. Manufactured interferon is used as an anticancer and antiviral drug.

Laparoscopy—Insertion of a tube through a very small surgical incision to remove tissue.

Loop electrosurgical excision procedure (LEEP)—Cone biopsy performed with a wire that is heated by electrical current.

Lymph nodes—Small, bean-shaped masses of tissue scattered along the lymphatic system that act as filters and immune monitors, removing fluids, bacteria, or cancer cells that travel through the lymph system. Cancer cells in the lymph nodes are a sign that the cancer has spread, and that it might recur.

Pelvic exenteration—Extensive surgery to remove the uterus, ovaries, pelvic lymph nodes, part or all of the vagina, and the bladder, rectum, and/or part of the colon.

Squamous cells—Thin, flat cells of the surfaces of the skin and cervix and linings of various organs.

Squamous intraepithelial lesion (SIL)—Abnormal growth of squamous cells on the surface of the cervix.

Vaginal stenosis—Narrowing of the vagina due to a build–up of scar tissue.

inflammation from bacteria or yeast infections. A few months after the infection is treated, the Pap test is repeated.

Biopsy

Following an abnormal Pap test, a **colposcopy** is usually performed. The physician uses a magnifying scope to view the surface of the cervix. The cervix may be coated with an iodine solution that causes normal cells to turn brown and abnormal cells to turn white or yellow. This procedure is called a Schiller test. If any abnormal areas are observed, a colposcopic biopsy may be performed. A biopsy is the removal of a small piece of tissue for microscopic examination by a pathologist.

Other types of cervical biopsies may be performed. An endocervical curettage is a biopsy in which a narrow instrument called a curette is used to scrape tissue from inside the opening of the cervix. A cone biopsy, or conization, is used to remove a cone-shaped piece of tissue from the cervix. In a cold knife cone biopsy, a surgical scalpel or laser is used to remove the tissue. A loop electrosurgical excision procedure (LEEP) is a cone biopsy using a wire that is heated by an electrical current. Cone biopsies can be used to determine whether abnormal cells have invaded below the surface of the cervix. They also can be used to treat many precancers and very early cancers. Biopsies may be performed using a local or general **anesthesia**. They may cause cramping and bleeding.

Diagnosing the cancer stage

Following a diagnosis of cervical cancer, various procedures may be used to stage the disease (determine how far the cancer has spread). For example, additional pelvic exams may be performed under anesthesia.

Several procedures help to determine if cervical cancer has invaded the urinary tract. With **cystoscopy**, a lighted tube with a lens is inserted through the

WWW.BOOKBAZ.IR

urethra (the urine tube from the bladder to outside the body) and into the bladder to examine these organs for cancerous cells. Tissue samples may be removed for microscopic examination by a pathologist. **Intravenous urography** (intravenous pyelogram or IVP) is an x ray of the urinary system, following the injection of special dye. The kidneys remove the dye from the bloodstream and the dye passes into the ureters (the tubes from the kidneys to the bladder) and bladder. IVP can detect a blocked ureter caused by the spread of cancer to the pelvic lymph nodes.

A procedure called proctoscopy or **sigmoidoscopy** is similar to cystoscopy. It is used to determine whether the cancer has spread to the rectum or lower part of the large intestine.

Computed tomography (CT or CAT) scans, **ultrasound**, or other imaging techniques may be used to determine the spread of cancer to various parts of the body. With a CT scan, an x-ray beam rotates around the body, taking images from various angles. It is used to determine if the cancer has spread to the lymph nodes. **Magnetic resonance imaging** (MRI), which uses a magnetic field to image the body, sometimes is used for evaluating the spread of cervical cancer. Chest x rays may be used to detect cervical cancer that has spread to the lungs.

Cancer staging

The FIGO system of staging

Staging the cancer is important, as treatment depends in large part on how far the cancer has developed and spread. The International Federation of Gynecologists and Obstetricians (FIGO) system usually is used to stage cervical cancer:

- Stage 0: Carcinoma in situ; non invasive cancer that is confined to the layer of cells lining the cervix.
- Stage I: Cancer that has spread into the connective tissue of the cervix but is confined to the uterus.
- Stage IA: Very small cancerous area that is visible only with a microscope.
- Stage IA1: Invasion area is less than 0.1 in (0.3 mm) deep and 0.3 in (7 mm) wide.
- Stage IA2: Invasion area is 0.1–0.2 in (3–5 mm) deep and less than 0.3 in (7 mm) wide.
- Stage IB: Cancer can be seen without a microscope or is deeper than 0.2 in (5 mm) or wider than 0.3 in (7 mm).
- Stage IB1: Cancer is no larger than 2 in (4 cm).
- Stage IB2: Stage IB cancer is larger than 2 in (4 cm).
- Stage II: Cancer has spread from the cervix but is confined to the pelvic region.
- Stage IIA: Cancer has spread to the upper region of the vagina, but not to the lower one-third of the vagina.
- Stage IIB: Cancer has spread to the parametrial tissue adjacent to the cervix.
- Stage III: Cancer has spread to the lower one-third of the vagina or to the wall of the pelvis and may be blocking the ureters.
- Stage IIIA: Cancer has spread to the lower vagina but not to the pelvic wall.
- Stage IIIB: Cancer has spread to the pelvic wall and/or is blocking the flow of urine through the ureters to the bladder.
- Stage IV: Cancer has spread to other parts of the body.
- Stage IVA: Cancer has spread to the bladder or rectum.
- Stage IVB: Cancer has spread to distant organs such as the lungs.
- Recurrent: Following treatment, cancer has returned to the cervix or some other part of the body.

Treatment

Sometimes cervical cancer must be treated immediately, but more often there is time to get a second opinion. In addition to the stage of the cancer, factors such as a woman's age, general health, and preferences may influence the choice of treatment. The exact location of the cancer within the cervix and the type of cervical cancer also are important considerations.

The standard treatments for cervical cancer are surgery, **radiation therapy**, and **chemotherapy**. Studies have shown that a combination of radiation therapy and chemotherapy reduces the death rate by 30–50%.

Treatment of precancer and carcinoma in situ

Most low-grade SILs that are detected with Pap tests revert to normal without treatment. Most high-grade SILs require treatment. Treatments to remove precancerous cells include:

- cold knife cone biopsy
- LEEP
- cryosurgery (freezing the cells with a metal probe)
- cauterization or diathermy (burning off the cells)
- laser surgery (burning off the cells with a laser beam)

These methods also may be used to treat cancer that is confined to the surface of the cervix (stage 0)

and other early-stage cervical cancers in women who may want to become pregnant. They may be used in conjunction with other treatments. These procedures may cause bleeding or cramping. All of these treatments require close follow-up to detect any recurrence of the cancer.

Surgery

Surgical treatments include:

- conization
- LEEP
- laser surgery for a surface lesion or tumor
- cryosurgery
- total vaginal hysterectomy (removal of the uterus and cervix through the vagina)
- total abdominal hysterectomy (removal of the uterus and cervix through a large abdominal incision)
- total laparoscopic hysterectomy (removal of the uterus and cervix with a laparoscope through a small abdominal incision)
- bilateral salpingo–oophorectomy (removal of the ovaries and fallopian tubes)
- radical hysterectomy (removal of the uterus, cervix, a portion of the vagina, and possibly the ovaries, fallopian tubes, and nearby lymph nodes)
- pelvic exenteration (removal of the uterus, cervix, ovaries, nearby lymph nodes, lower colon, rectum, and bladder, with construction of artificial openings for collecting feces and urine and possible plastic surgery to construct an artificial vagina).

Radiation

External radiation therapy uses high-energy x rays applied to the outside of the body to kill cancer cells. With internal radiation therapy thin tubes or implants containing a radioactive substance are placed in the vagina for a few hours or up to three days, two or more times over a period of several weeks.

Radiation therapy to the pelvic region can have many side effects:

- skin reaction in the area of treatment
- fatigue
- upset stomach and loose bowels
- vaginal stenosis (narrowing of the vagina due to build–up of scar tissue) leading to painful sexual intercourse
- premature menopause in young women
- problems with urination

Chemotherapy

Chemotherapy uses one or more drugs to kill cancer cells. It is used to treat disease that has spread beyond the cervix. The common drugs used for cervical cancer are cisplatin (Platinol), 5–fluorouracil (Efudex, Adrucil, Fluoroplex), ifosfamide (Ifex), paclitaxel (Taxol), and topotecan (Hycamtin). These drugs may be injected or taken by mouth.

The side effects of chemotherapy depend on a number of factors, including the type of drug, the dosage, and the length of the treatment. Side effects may include:

- nausea and vomiting
- fatigue
- changes in appetite
- hair loss (alopecia)
- mouth or vaginal sores
- infections
- menstrual cycle changes
- premature menopause
- infertility
- bleeding or anemia (low red blood cell count) With the exception of **menopause** and **infertility**, most of the side effects are temporary.

Treatment by stage

Common treatment options by stage are:

- O—conization; LEEP; laser surgery; cryosurgery; total hysterectomy for women who cannot or do not want to have children; internal radiation therapy for women who cannot have surgery
- IA—conization; total hysterectomy with or without bilateral salpingo–oophorectomy; radical hysterectomy with removal of lymph nodes; internal radiation therapy
- IB, IIA—combination internal and external radiation therapy; radical hysterectomy with removal of lymph nodes, possibly followed by radiation therapy and chemotherapy; radiation therapy plus chemotherapy
- IIB, III, IVA—internal and external radiation therapy and chemotherapy
- IVB—radiation therapy to relieve symptoms and improve quality of life; chemotherapy
- recurrent—pelvic exenteration followed by radiation therapy and chemotherapy; chemotherapy to relieve symptoms and improve quality of life.

WWW.BOOKBAZ.IR

Alternatives

Many complementary and alternative medicine (CAM) treatments claim to help prevent or cure various cancers. Complementary therapies are those used in addition to traditional Western medicine, while alternative therapies are used in place of conventional Western medicine. CAM treatments include **acupuncture**, bodywork therapies such as massage and **reflexology**, homeopathy, and herbal remedies used in **traditional Chinese medicine** or **Ayurvedic medicine** (traditional Indian medicine). Complementary and alternative treatment of cancer is a complicated arena. In some cases CAM is effective in relieving or reducing the symptoms associated with cancer and cancer treatment. Nevertheless, CAM treatments may interact with each other and with conventional treatments in ways that are not always well understood but that may alter the expected treatment results. In the United States, the National Center for Complementary and Alternative Medicine (NCCAM) within the National Institutes of Health supervises clinical trials of many CAM cancer therapies. Individuals should discuss all CAM therapies with their physician before beginning a treatment.

Certain foods, mainly vegetables, fruits, and grains, are believed by many people to offer protection against various cancers. As of 2014, the American Cancer Society (ACS) recommended a diet high in fruits, vegetables, and whole grains and low in calories and fats as the best way to maintain health. The ACS does not recommend taking mega-doses of any dietary supplements to cure or reduce the risk any cancer.

Prognosis

For cervical cancers that are diagnosed in the pre-invasive stage, the five-year-survival rate is almost 100%. When cervical cancer is detected in the early invasive stages, approximately 91% of women survive five years or more. Stage IVB cervical cancer is not considered curable. The five-year-survival rate for all cervical cancers combined is about 70%. The death rate from cervical cancer in the United States continues to decline by about 2% each year. Women over age 65 account for 40–50% of all deaths from cervical cancer.

Prevention

A vaccine introduced in 2006, Gardasil®, protects against four HPV viruses that cause 70% of cervical cancers and 90% of genital **warts**. The vaccine is most effective when given before a female becomes sexually active. It is recommended for all women ages 11–18 and may be given as young as age nine. Women ages 19–26 also may be vaccinated at the discretion of their physician. The vaccine is given in three doses over a six–month period and is covered by most health insurance programs. A second vaccine, Cervarix, was released in 2009 and protects against two types of HPV.

Since **vaccination** does not provide complete protection against all HPV viruses, sexual behaviors can put women at risk for HPV infection and cervical cancer. These behaviors include:

- sexual intercourse at age 16 or younger
- partners who began having intercourse at a young age
- multiple sexual partners
- sexual partners who have had multiple partners ("high-risk")
- a partner who has had a previous sexual partner with cervical cancer

HPV infection may not produce any symptoms, so sexual partners may not know that they are infected. However, Pap tests can detect the infection. A DNA screening test for HPV can be done at the same time as the Pap test. **Condoms** do not necessarily prevent HPV infection.

Infection with the human **immunodeficiency** virus (HIV) that causes acquired immunodeficiency syndrome (**AIDS**) is a risk factor for cervical cancer. Women who test positive for HIV may have impaired immune systems that cannot correct precancerous conditions. Furthermore, sexual behavior that puts women at risk for HIV infection, also puts them at risk for HPV infection. There is some evidence suggesting that another sexually transmitted virus, the **genital herpes** virus, also may be involved in cervical cancer.

Smoking may double the risk of cervical cancer. Chemicals produced by tobacco smoke can damage the DNA of cervical cells. The risk increases with the number of years a woman smokes and the amount she smokes. A 2003 study also linked smoking to poorer outcomes and survivals in cervical cancer patients.

Most cases of cervical cancers are preventable, since they start with easily detectable precancerous changes. Therefore, the best prevention for cervical cancer is to have regular Pap tests. The American Cancer Society recommends that women begin having Pap tests about three years after first having sexual intercourse, but no later than 21 years of age. Women should continue screening every year with regular Pap tests until age 30. Once a woman has had three normal

results in a row, she may get screened every two to three years. A doctor may suggest more frequent screening if a woman has certain risk factors for cervical cancer. Women who have had total hysterectomies including the removal of the cervix and those over age 70 who have had three normal results generally do not need to continue having Pap tests under these guidelines.

The National Breast and Cervical Cancer Early Detection Program provides free or low–cost Pap tests and treatment for women without health insurance, for older women, and for members of racial and ethnic minorities. The program is administered through individual states, under the direction of the Centers for Disease Control and Prevention.

REVISED BY TISH DAVIDSON, A.M.

Cervical conization

Definition

Cervical conization is both a diagnostic and treatment tool used to detect and treat abnormalities of the cervix. It is also known as a cone biopsy or cold knife cone biopsy.

Purpose

Cervical conization is performed if the results of a cervical biopsy have found a precancerous condition in the cervix. The cervix is the small cylindrical organ at the lower part of the uterus, which separates the uterus from the vagina. Cervical conization also may be performed if there is an abnormal cervical smear test (**Pap test**). A biopsy is a diagnostic test in which tissue or cells are removed from the body and examined under a microscope, primarily to look for cancer or other abnormalities.

Precautions

As with any operation that is performed under general **anesthesia**, the patient must not eat or drink anything for six to eight hours before surgery.

Description

The patient lies on the table with her legs raised in stirrups, similar to the position when having a Pap test. The patient is given general anesthesia, and the vagina is held open with an instrument called a speculum. Using a scalpel or laser the doctor removes a cone-shaped piece of the cervix containing the area with abnormal cells. The resulting crater is repaired by stitching flaps of tissue over the wound. Alternatively, the wound may be left open, and heat or freezing is used to stop bleeding.

Once the tissue has been removed, it is examined under a microscope for signs of cancer. If cancer is present, other tests will be needed. Surgery will be performed to remove the cervix and uterus (**hysterectomy**) and other treatments may be used as well. If the abnormal cells are precancerous, a laser can be used to destroy them.

Cold knife cone biopsy used to be the preferred treatment for removing abnormal cells in the cervix. Now, most cone biopsies are performed using **laser surgery**. Cold knife cone biopsy is generally used only for special situations. For example, if a biopsy did not remove all the abnormal cells, the cold knife cone procedure allows the physician to remove what's left.

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—The removal of a small piece of living tissue for examination under a microscope.

Pap test—The short term for Papanicolaou test, this procedure tests a smear of cellular material scraped from the cervix and examined under a microscope to detect abnormal cells.

Aftercare

An overnight stay in the hospital may be required. After the test, the patient may feel some cramps or discomfort for about a week. Women should not have sex, use tampons, or douche until after seeing their physician for a follow up appointment (a week or more after the procedure).

Results

This procedure is only performed if an abnormality is known or suspected.

Risks

Because cone biopsies carry risks such as bleeding and problems with subsequent pregnancies, they have been replaced with newer technologies except in a few circumstances.

About one in 10 women experience bleeding from the vagina about two weeks after the biopsy. There is also a slight risk of infection or perforation of the uterus. In a few women, the cervical canal becomes narrowed or completely blocked, which can later interfere with the movement of sperm. This can impair a woman's fertility.

If too much muscle tissue has been removed, the procedure can lead to an **incompetent cervix**, which can be a problem with subsequent pregnancies. An incompetent cervix cannot seal properly to maintain a **pregnancy**. If untreated, the condition increases the odds of **miscarriage** or **premature labor**.

Cervical conization also may temporarily alter cervical cells, which can make a Pap smear test hard to interpret accurately for three or four months.

Abnormal results

The presence of precancerous or cancerous cells in the cervix.

Carol A. Turkington

Cervical disk disease

Definition

Cervical disk disease refers to a gradual deterioration of the spongy disks in the top part of the spine.

Description

The spine is made up of 33 bones called vertebrae that are separated by spongy rings of elastic material. These rings, known as disks, are often compared to shock absorbers because they help to cushion the vertebrae. Just as importantly, they also make it possible to turn the head and neck. Over time, these disks slowly become flattened and less elastic due to everyday wear and tear. When this process occurs in the disks of the neck, it is referred to as cervical disk disease. Other general terms for this process include degenerative disk disease and intervertebral disk disease.

Cervical disk disease affects everyone to some degree, often without causing any bothersome symptoms. However, this condition can also lead to specific problems related to nerve functioning. For example, the outer edge of a disk may tear, allowing the gelatinous material inside to bulge outward (**herniated disk**). This can put pressure on nerves that exit the spine. Two adjacent vertebrae may rub together (sometimes resulting in bone spurs) that can also pinch these nerves. In other cases, the inner part of the ring may push on the spinal cord itself, which passes through the disk. Any of these situations can cause **pain** and limit movement. While symptoms primarily affect the neck, they can also occur in other parts of the body.

Causes and symptoms

Cervical disk disease is a gradual process that occurs with **aging**, though poor posture, repeated lifting, and tobacco use can hasten its course. Symptoms include pain when moving the neck and limited neck movement. The condition can also affect the hand, shoulder, and arm resulting in pain, numbness/tingling, and weakness. If the spinal cord itself is affected,

KEY TERMS

Bone spur—An overgrowth of bone.

Cervical—Relating to the top part of the spine that is composed of the seven vertebrae of the neck and the disks that separate them.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body.

Magnetic resonance imaging—A type of imaging that uses magnetic fields to generate a picture of internal structures.

Myelography—An imaging procedure involving the injection of a radioactive dye into the fluid surrounding the spine. A myelography can be used to detect herniated disks, nerve root damage, and other problems affecting the cervical spine.

Neurologist—A doctor who specializes in disorders of the brain and central nervous system.

Orthopedist—A doctor who specializes in disorders of the musculoskeletal system.

these symptoms may occur in the legs. Loss of bowel or bladder control may also occur.

Diagnosis

Cervical disk disease is typically diagnosed by an orthopedist or a neurologist. After taking a medical history and conducting a **physical examination**, the doctor will recommend an imaging procedure to gather more information about the nature of the problem. This may include an x ray, a CT scan, an MRI, or **myelography**. In addition, an **electromyography** may be used to evaluate the functioning of nerves in the arms, hands, or legs. Cervical disk disease is typically covered by medical insurance.

Treatment

Treatment usually involves **physical therapy**, several weeks of drug therapy with **nonsteroidal anti-inflammatory drugs** (NSAIDs), and limited use of a cervical collar (to reduce neck movement). Neck **traction** and **heat treatments** may also be recommended. In some cases, **steroids** or anesthetic drugs may be injected into the spinal canal to help alleviate symptoms. Aside from these measures, maintaining good posture and placing a pillow under the neck and head during sleep can be helpful. Treatment may last anywhere from several weeks to three months or more. Neck surgery is not usually advised unless other therapies have failed.

Alternatives

Acupuncture, therapeutic massage, and **yoga** are believed by some practitioners of alternative medicine to have generalized pain-relieving effects. However, any therapy that involves manipulating the neck is not recommended and should be approved by primary doctor beforehand.

Prognosis

In most people symptoms go away within three months if not sooner. A smaller number may require surgery to correct the problem.

Prevention

While some degree of disk degeneration is inevitable, people can reduce their risk by practicing good posture (during sitting, standing, and lifting), performing neck-stretching exercises, maintaining an ideal weight, and quitting **smoking**.

Greg Annussek

Cervical osteoarthritis *see* **Cervical spondylosis**

Cervical spondylosis

Definition

Cervical spondylosis refers to common age-related changes in the area of the spine at the back of the neck. With age, the vertebrae (the component bones of the spine) gradually form bone spurs, and their

WWW.BOOKBAZ.IR

shock-absorbing disks slowly shrink. These changes can alter the alignment and stability of the spine. They may go unnoticed, or they may produce problems related to pressure on the spine and associated nerves and blood vessels. This pressure can cause weakness, numbness, and **pain** in various areas of the body. In severe cases, walking and other activities may be compromised.

Description

As it runs from the brain down the back, the spinal cord is protected by ringlike bones, called vertebrae, stacked one upon the other. The vertebrae are not in direct contact with one another, however. The intervening spaces are filled with structures called disks. The disks are made up of a tough, fibrous outer tissue with an inner core of elastic or gel-like tissue.

One of the most important functions of disks is protecting the vertebrae and the nerves and blood vessels between the vertebrae. The disks also lend flexibility to the spinal cord, facilitating movements such as turning the head or bending the neck. As people age, disks gradually become tougher and more unyielding. Disks also shrink with age, which reduces the amount of padding between the vertebrae.

As the amount of padding shrinks, the spine loses stability. The vertebrae react by constructing osteophytes, commonly known as bone spurs. There are seven vertebrae in the neck; development of osteophytes on these bones is sometimes called cervical **osteoarthritis**. Osteophytes may help to stabilize the degenerating backbone and help protect the spinal cord.

By age 50, 25–50% of people develop cervical spondylosis; by 75 years of age, it is seen in at least 70% of people. Although shrunken vertebral disks, osteophyte growth, and other changes in their cervical spine may exist, many of these people never develop significant problems.

However, about 50% of people over age 50 experience neck pain and stiffness due to cervical spondylosis. Of these people, 25–40% have at least one episode of cervical radiculopathy, a condition that arises when osteophytes compress nerves between the vertebrae. Another potential problem occurs if osteophytes, degenerating disks, or shifting vertebrae narrow the spinal canal. This pressure compresses the spinal cord and its blood vessels, causing cervical spondylitic myelopathy, a disorder in which large segments of the spinal cord are damaged. This disorder affects fewer than 5% of people with cervical spondylosis. Symptoms of both cervical spondylitic myelopathy and cervical radiculopathy may be present in some people.

Causes and symptoms

As people age, shrinkage of the vertebral disks prompts the vertebrae to form osteophytes to stabilize the back bone. However, the position and alignment of the disks and vertebrae may shift despite the osteophytes. Symptoms may arise from problems with one or more disks or vertebrae.

Osteophyte formation and other changes do not necessarily lead to symptoms, but after age 50, half of the population experiences occasional neck pain and stiffness. As disks degenerate, the cervical spine becomes less stable, and the neck is more vulnerable to injuries, including muscle and ligament strains. Contact between the edges of the vertebrae can also cause pain. In some people, this pain may be referred—that is, perceived as occurring in the head, shoulders, or chest, rather than the neck. Other symptoms may include vertigo (a type of **dizziness**) or ringing in the ears.

The neck pain and stiffness can be intermittent, as can symptoms of radiculopathy. Radiculopathy refers to compression on the base, or root, of nerves that lead away from the spinal cord. Normally, these nerves fit comfortably through spaces between the vertebrae. These spaces are called intervertebral foramina. As the osteophytes form, they can impinge on this area and gradually make the fit between the vertebrae too snug.

The poor fit increases the chances that a minor incident, such as overdoing normal activities, may place excess pressure on the nerve root, sometimes referred to as a pinched nerve. Pressure may also accumulate as a direct consequence of osteophyte formation. The pressure on the nerve root causes severe shooting pain in the neck, arms, shoulder, and/or upper back, depending on which nerve roots of the cervical spine are affected. The pain is often aggravated by movement, but in most cases, symptoms resolve within four to six weeks.

Cervical spondylosis can cause cervical spondylitic myelopathy through stenosis- or osteophyte-related pressure on the spinal cord. **Spinal stenosis** is a narrowing of the spinal canal—the area through the center of the vertebral column occupied by the spinal cord. Stenosis occurs because of misaligned vertebrae and out-of-place or degenerating disks. The problems created by spondylosis can be exacerbated if a person has a naturally narrow spinal canal. Pressure against the spinal cord can also be created by osteophytes forming on the inner surface of vertebrae and pushing against the spinal cord. Stenosis or osteophytes can compress the spinal cord and its blood vessels,

impeding or **choking** off needed nutrients to the spinal cord cells; in effect, the cells starve to death.

With the death of these cells, the functions that they once performed are impaired. These functions may include conveying sensory information to the brain or transmitting the brain's commands to voluntary muscles. Pain is usually absent, but a person may experience leg numbness and an inability to make the legs move properly. Other symptoms can include clumsiness and weakness in the hands, stiffness and weakness in the legs, and spontaneous twitches in the legs. A person's ability to walk is affected, and a wide-legged, shuffling gait is sometimes adopted to compensate for the lack of sensation in the legs and the accompanying, realistic fear of falling. In very few cases, bladder control becomes a problem.

Diagnosis

Cervical spondylosis is often suspected based on the symptoms and their history. Careful neurological examination can help determine which nerve roots are involved, based on the location of the pain and numbness, and the pattern of weakness and changes in reflex responses. To confirm the suspected diagnosis, and to rule out other possibilities, imaging tests are ordered. The first test is an x ray. X rays reveal the presence of osteophytes, stenosis, constricted space between the vertebrae, and misalignment in the cervical spine—in short, an x ray confirms that a person has cervical spondylosis. To demonstrate that the condition is causing the symptoms, more details are needed. Other imaging tests, such as **magnetic resonance imaging** (MRI) and computed tomography **myelography**, help assess effects of cervical spondylosis on associated nerve tissue and blood vessels.

An MRI may be preferred, because it is a non invasive procedure and does not require injecting a contrast medium as does computed tomography myelography. MRIs also have greater sensitivity for detecting disk problems and spinal cord involvement, and the test allows the physician to create images of a larger area from various angles. However, these images may not show enough detail about the vertebrae themselves. Computed tomography myelography yields a superior image of the bones involved in cervical spondylosis. Added benefits include that it takes less time to perform and tends to be less expensive than an MRI. A good diagnosis may be reached with either a computed tomography myelography or an MRI, but sometimes complementary information from both tests is necessary. Nerve conduction velocity, electromyogram (EMG), and/or somatosensory evoked potential testing may help to confirm which nerve roots are involved.

Treatment

When possible, conservative treatment of symptoms is preferred. Conservative treatment begins with rest—either restricting normal activities to a less strenuous level or bed rest for three to five days. If rest is not adequate to relieve symptoms, a cervical orthosis may be prescribed, such as a soft cervical collar or stiffer neck brace to restrict neck movement and shift some of the head's weight from the neck to the shoulders. Cervical **traction** may also be suggested, either at home with the advice of a physical therapist or in a health-care setting.

Pain is treated with **nonsteroidal anti-inflammatory drugs**, such as naprosen or ibuprofen. If these drugs are ineffective, a short-term prescription for **corticosteroids** or **muscle relaxants** may be given. For chronic pain, tricyclic antidepressants can be prescribed. Although these drugs were developed to treat depression, they are also effective in treating pain. Once any pain is resolved, exercises to strengthen neck muscle and preserve flexibility are prescribed.

If the pain is severe, a short treatment of epidural corticosteroids may be prescribed with discretion. A corticosteroid such as prednisone can be combined with an anesthetic and injected with a long needle into the space between the damaged disk and the covering of the nerve and spinal cord. Injection into the cervical epidural space relieves severe pain that is not managed with conventional treatment. Frequent use of this treatment is not medically recommended and is used only if the more conservative therapy is not effective.

If pain is continuous and does not respond to conservative treatment, surgery may be suggested. Surgery is usually not recommended for neck pain, but it may be necessary to address radiculopathy and myelopathy. Surgery is particularly recommended for people who have already developed moderate to severe symptoms of myelopathy, although age or poor health may prohibit that recommendation. The specific details of the surgery depend on the structures involved, but the overall goal is to relieve pressure on the nerve root, spinal cord, or blood vessels and to stabilize the spine.

Alternatives

Alternative therapy is not meant to replace conventional medical treatment, but it can be a useful adjunct. Its main roles are to relieve tension, manage

WWW.BOOKBAZ.IR

KEY TERMS

Alexander technique—A technique developed by Frederick Alexander that focuses on the variations in body posture, muscles, and breathing. Defects in these functions can lead to stress, nervous tension or possible loss of function.

Bone spur—Also called an osteophyte, it is an outgrowth or ridge that forms on a bone.

Cervical—Referring to structures within the neck.

Computed tomography myelography—This medical procedure combines aspects of computed tomography scanning and plain-film myelography. A CT scan is an imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures. Myelography involves injecting a water-soluble substance into the area around the spine to make it visible on x rays. In computed tomography myelography or CT myelography, the water-soluble substance is injected, but the imaging is done with a CT scan.

Disk—A ringlike structure that fits between the vertebrae in the spine to protect the bones, nerves, and blood vessels. The outer layer is a tough, fibrous tissue, and the inner core is composed of more elastic tissue.

Feldenkrais method—A therapy based on creating a good self image by correction and improvements of body movements.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Myelopathy—A disorder in which the tissue of the spinal cord is diseased or damaged.

Orthosis—An external device, such as a splint or a brace, that prevents or assists movement.

Osteophyte—Also referred to as bone spur, it is an outgrowth or ridge that forms on a bone.

Radiculopathy—Sometimes referred to as a pinched nerve, it refers to compression of the nerve root—the part of a nerve between vertebrae. This compression causes pain to be perceived in areas to which the nerve leads.

Spine—A term for the backbone that includes the vertebrae, disks, and spinal cord as a whole.

Stenosis—A condition in which a canal or other passageway in the body is constricted.

Traction—A medical treatment that exerts a pulling or extending force. Used for cervical problems, it relieves pressure on structures between the vertebrae and muscular tension.

Vertebrae—The ringlike component bones of the spine.

pain, and strengthen neck and back muscles. Massage is one way to relieve tension, and **yoga** provides the additional benefit of strengthening muscles. **Chiropractic** and **acupuncture** have been reported to relieve the pain associated with disk problems, although great care needs to be taken to avoid exacerbating them. Practitioners of the **Alexander technique** or the **Feldenkrais method** can provide instruction on correct posture and **exercise** that may help prevent further symptoms. Vitamin and mineral supplementation along with herbal therapies and homeopathy can help build and rebalance the weakened structure.

Prognosis

The gradual progression of cervical spondylosis cannot be stopped; however, it doesn't always cause symptoms. For the individuals who do experience problems, conservative treatment is very effective in managing the symptoms. Nearly all people with neck pain, approximately 75% of persons with radiculopathy, and up to 50% of people with myelopathy find relief through therapy alone. For the remaining people with radiculopathy or myelopathy, surgery may be recommended. Surgery is deemed successful in 70–80% of cases.

Prevention

Since cervical spondylosis is part of the normal **aging** process, not much can be done to prevent it. It may be possible to ward off some or all of the symptoms by engaging in regular physical exercise and limiting occupational or recreational activities that place pressure on the head, neck, and shoulders. The best exercises for the health of the cervical spine are noncontact activities, such as swimming, walking, or yoga. Once symptoms have already developed, the emphasis is on symptom management rather than prevention.

KEY TERMS

Cryotherapy—Freezing the affected tissue.

Electrocoagulation—Using electrical current to cauterize the affected tissue.

LEEP—Loop Electrosurgical Excision Procedure.

Cervicitis

Definition

Cervicitis is an inflammation of the cervix.

Description

Cervicitis is a inflammation of the cervix (the opening into the uterus). This inflammation can be chronic and may or may not have an identified cause.

Causes and symptoms

The most common cause of cervicitis is infection, either local or as a result of various sexually transmitted diseases, such as chlamydia or **gonorrhea**. Cervicitis can also be caused by birth control devices such as a cervical cap or diaphragm, or chemical exposure. Other risk factors include multiple sexual partners or cervical **trauma** following birth. In postmenopausal women, cervicitis is sometimes related to a lack of estrogen.

Although a woman may not notice any signs of infection, symptoms of cervicitis include the following:

- persistent unusual vaginal discharge
- abnormal bleeding, either between periods or following sexual intercourse
- painful sexual intercourse
- vaginal pain
- frequent need to urinate
- burning or itching in the vaginal area

Diagnosis

The standard method of diagnosing cervicitis is through a pelvic examination or a Pap smear. During the **pelvic exam**, the physician usually swabs the affected area, and then sends the tissue sample to a laboratory. The laboratory tries to identify the specific organism responsible for causing the cervicitis. A biopsy to take a sample of tissue from the affected area is sometimes required in order to rule out cancer. **Colposcopy**, a procedure used to look at the cervix under a microscope, may also be used to rule out cancer.

Treatment

The first course of treatment for cervicitis is usually **antibiotics**. If these medicines do not cure the cervicitis, other treatment options include:

- Loop Electrosurgical Excision Procedure (LEEP)
- cryotherapy
- electrocoagulation
- laser treatment

Prognosis

Cervicitis will usually be cured when the course of therapy is complete. Severe cases, however, may last for a few months, even after the therapy is complete. If the cervicitis was caused by a sexually transmitted disease, both partners should be treated with medication.

Prevention

Practicing safe sexual behavior, such as monogamy, is one way of lowering the prevalence of cervicitis. In addition, women who began sexual activity at a later age have been shown to have a lower incidence of cervicitis. Another recommendation is to use a latex condom consistently during intercourse. If the cervicitis is caused by any sexually transmitted disease, the patient is advised to notify all sexual partners.

Cesarean section

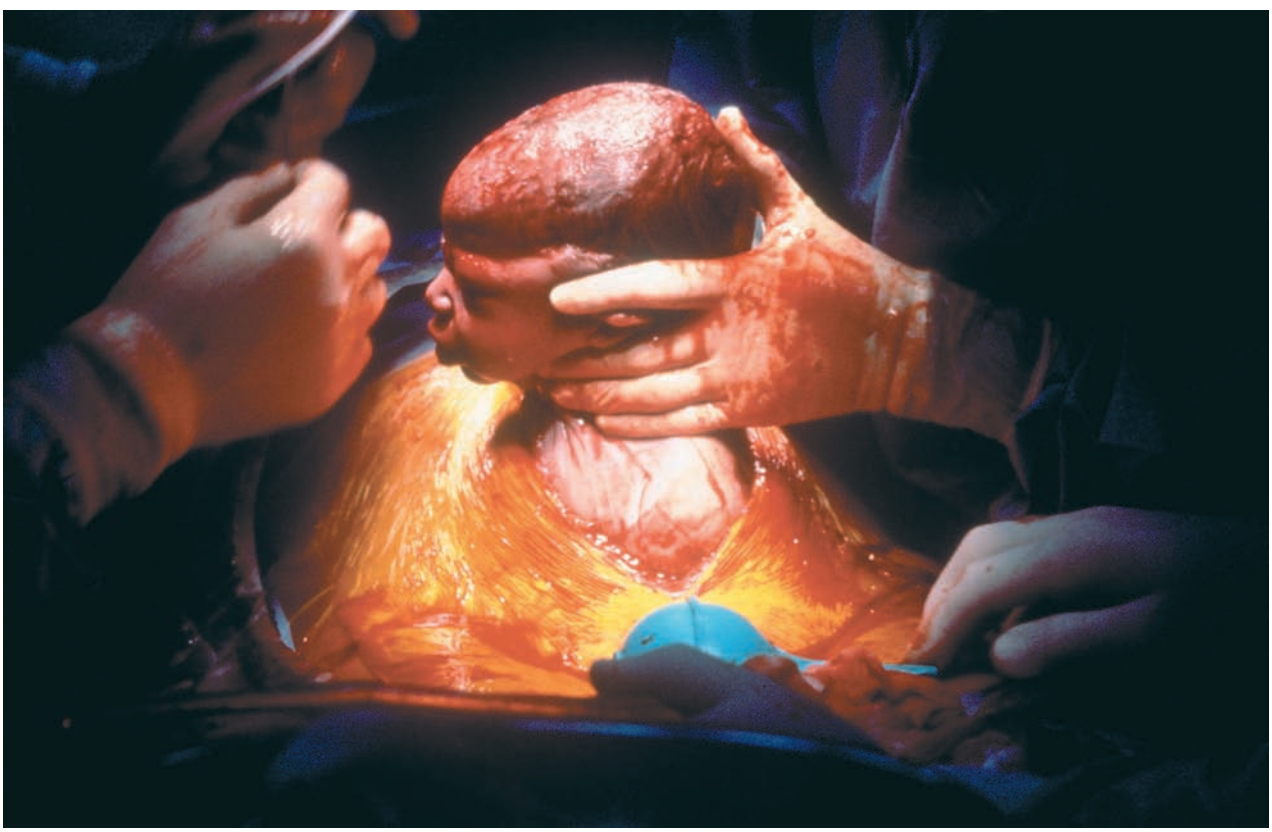
Definition

A cesarean section is a surgical procedure in which a fetus is delivered through incisions made in the mother's abdominal and uterine walls. The procedure is commonly called a cesarean delivery or c-section.

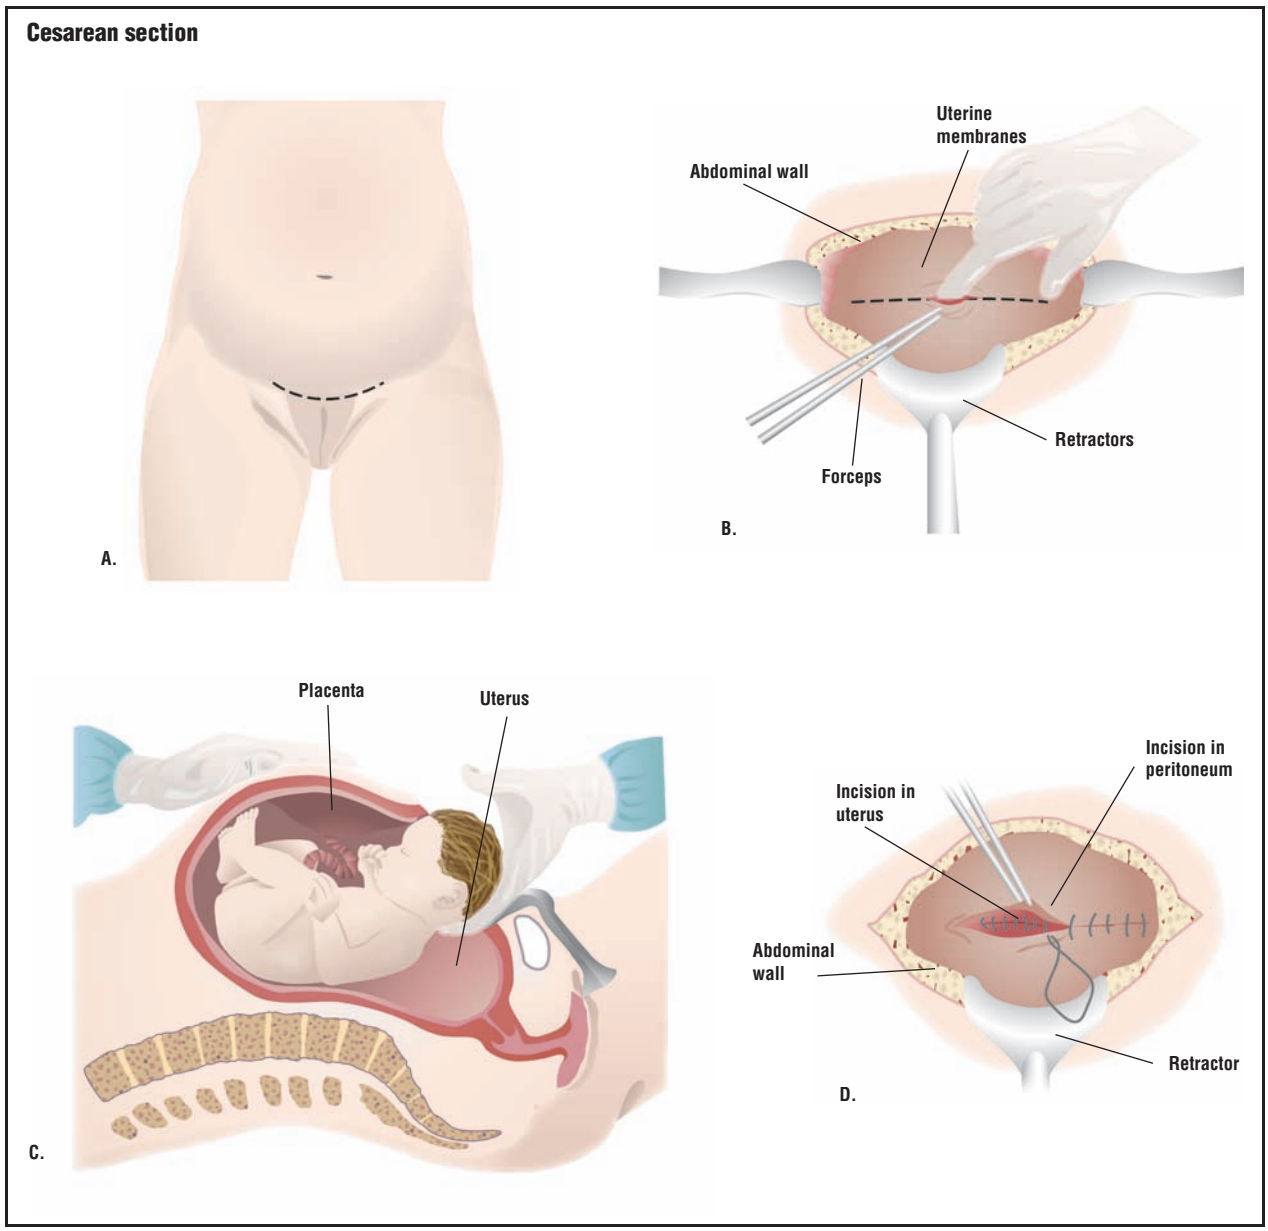
Purpose

Medical indications

C-sections are performed for a variety of reasons. Emergency c-sections are performed when the life or health of the mother or infant is threatened by complications of labor and/or vaginal delivery. The most common reason for cesarean delivery is that the mother had a previous c-section. The second most common reason is dystocia—difficult or nonprogressive labor. Dystocia is most commonly caused by abnormalities of the birth canal, an abnormality in the position of the fetus, or abnormalities of labor, including weak or infrequent contractions. Sometimes the mother's pelvic structure prevents adequate passage of the fetus. Cephalopelvic disproportion (CPD) is a condition in which the baby's head is too large for the mother's pelvis. In about 3% of all births, the baby is in a breech presentation (buttocks or feet first), which commonly results in cesarean delivery. C-sections are also performed when the fetus is in a transverse position, lying horizontally across the pelvis, sometimes with a shoulder in the birth canal.



This baby is being delivered by cesarean section. *(Custom Medical Stock Photo, Inc.)*



To remove a baby by cesarean section, an incision is made into the abdomen, usually just above the pubic hairline (A). The uterus is located and divided (B), allowing for delivery of the baby (C). After all the contents of the uterus are removed, the uterus is repaired and the rest of the layers of the abdominal wall are closed (D). *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

A variety of factors can lead to emergency cesarean deliveries. With a prolapsed umbilical cord, the cord is pushed into the vagina ahead of the baby and becomes compressed, cutting off the infant's blood flow. **Placental abruption** is the separation of the placenta from the uterine wall before the baby is born, again cutting off blood flow to the fetus. The risk of placental abruption is especially high with multiple births (twins, triplets, or more). With **placenta previa**, the placenta partially or completely covers the cervix, making vaginal delivery impossible. About 9% of c-sections are performed because of fetal distress. This can occur for a variety of reasons, such as the umbilical cord wrapping around the baby's neck. Fetal distress is often related to abnormalities in the position of the fetus or abnormalities in the birth canal that reduce blood flow through the placenta. When the fetal heart monitor registers an abnormal heart rate or rhythm, a c-section may prevent brain damage from fetal oxygen deprivation.

WWW.BOOKBAZ.IR

Maternal health conditions can result in either scheduled or emergency cesarean delivery. Maternal diabetes, **hypertension**, **genital herpes**, malignancies of the genital tract, or **preeclampsia** (high blood pressure related to **pregnancy**) may make cesarean delivery a safer choice. Certain fetal congenital malformations or skeletal disorders, or fetal or maternal infection may also necessitate cesarean delivery.

Choosing cesarean section

There has been a growing movement in developed countries to allow women to choose c-sections over vaginal deliveries despite the absence of any medical indications. Between 2% and 8% of all c-sections qualify as elective cesarean delivery on maternal request (CDMR). This trend is very controversial. In addition to increasing healthcare costs, it exposes the mother and infant to the risks inherent in major surgery.

Reasons for an elective, scheduled c-section include:

- convenience—choosing the date and time of delivery, thereby avoiding conflicts with work or family obligations
- physician preference—assuring that the mother's physician will be present for delivery
- avoiding the pain of labor and delivery
- avoiding risks of vaginal delivery, such as urinary or rectal incontinence, sexual dysfunction, dystocia, and maternal hemorrhage

Demographics

The incidence of cesarean sections increased steadily worldwide over the course of the twentieth century. The increase has been especially dramatic in the United States in recent decades—from 20.7% of births in 1996 to 32.8% in 2010. Rates of cesarean delivery have increased among women of all ages, races, ethnic groups, and gestational ages. The overall rate in most developed regions of the world is about 21.1%. It is 14.3% in less developed regions, and only about 2% in the least developed regions. Within the United States, rates of cesarean delivery vary as much as tenfold among different hospitals.

Description

Cesarean deliveries are considered major surgery and are usually performed under the strict conditions of a hospital operating room. The procedure is generally performed by an obstetrician.

Cesarean delivery is usually performed under spinal or epidural **anesthesia**. This allows the mother to remain awake during the surgery, avoids the risks of general anesthesia, and enables immediate contact between mother and child. Spinal anesthesia is injected between vertebrae of the lower back. Epidural anesthesia is administered through a catheter into the epidural space around the spinal cord, and the catheter may be left in place for additional anesthesia. Some women experience a drop in blood pressure with a regional anesthetic that can be countered with fluids and/or medications. General anesthesia, which can be administered more rapidly, may be used for emergency c-sections. Although the baby may be affected by anesthetics that cross the placenta, the effects are generally mild if delivery occurs within ten minutes after administering the anesthesia.

The first incision, called a laparotomy, is made through the abdominal wall. It is usually a horizontal incision across and above the pubic bone ("bikini cut"). Infrequently, the incision is vertical from just below the navel to the top of the pubic bone. The second incision, called a hysterotomy, is made through the uterine wall. This is usually a transverse incision that heals well and enables women to attempt vaginal delivery in the future. A classical vertical incision provides a larger opening and is used in critical situations such as placenta previa. A vertical incision causes more bleeding, presents a greater risk of abdominal infection, and leaves a weaker scar.

Once the uterus is opened, the amniotic sac is ruptured and the baby is delivered. The time from initial incision to birth is typically five minutes. The umbilical cord is clamped and cut, and the newborn is evaluated. The placenta is removed, and the mother's uterus and abdomen are stitched closed. Surgical staples may be used to close the outermost layer of the abdominal incision. This procedure may take 30–40 minutes; thus, the entire surgery can be performed in less than one hour.

Precautions

The recommendations for c-sections are aimed at reducing unnecessary cesarean deliveries. Reducing first cesarean deliveries is considered particularly important, since more than 90% of first cesareans lead to repeat cesareans with subsequent pregnancies:

- Unless immediate delivery is medically necessary, adequate time should be allowed for each stage of labor. Adequate times are now considered to be longer than previously acknowledged. Thus, protracted

labor alone should not be an indication for cesarean delivery.

- A diagnosis of failed induction of labor should be made only if regular contractions and cervical change have not occurred after at least 24 hours of induction with oxytocin and, if possible, artificial membrane rupture.
- External turning of the fetus, known as external cephalic version, is encouraged for breech presentations. Depending on the size of the mother's pelvis, the size of the baby, and the breech position, physicians may attempt a vaginal breech delivery; however, a c-section is safer if the baby is 8 lb (3.6 kg) or more, or in a breech position with the feet crossed or with the head hyperextended.
- Obstetricians should be conservative in diagnosing dystocia and fetal distress and should watch and wait before deciding to perform a cesarean. Better fetal heart rate interpretation, fetal scalp stimulation, and intrauterine resuscitation during labor are encouraged.

The U.S. National Institutes of Health and the Committee on Obstetric Practice of the American Congress of Obstetricians and Gynecologists (ACOG) recommend against CDMR in the absence of maternal or fetal indications for cesarean delivery. CDMR:

- is not appropriate for women desiring several future pregnancies
- is a potential risk for infant respiratory problems
- should not be performed before the 39th week of pregnancy or without verifying fetal lung maturity
- is associated with longer hospital stays and increased risk of placenta previa and placenta accreta (an abnormally firm attachment of the placenta) in subsequent deliveries
- should not be motivated by inadequate pain management

Because the classical vertical uterine incision used in the past left a weak scar that could rupture with subsequent deliveries, a cesarean section almost always meant that subsequent deliveries would be cesarean as well. However, the low transverse uterine incision in current use greatly decreases risk of rupture with subsequent deliveries, enabling many women to have a vaginal birth after a cesarean (VBAC). The success rate for VBAC is at least 70%. Trial of labor (TOL), a purposeful attempt to deliver vaginally, results in uterine rupture in only 0.2–1.5% of women with a low transverse uterine scar, compared to 12% for women with a classic uterine incision. ACOG recommends that VBAC be limited to women with full-term pregnancies (37–40 weeks) who have had only one previous low-transverse c-section. Nevertheless, many providers and facilities will not allow TOL after a cesarean, forcing women to undergo repeat cesareans.

Preparation

There are several procedures for diagnosing conditions that may require a c-section. **Ultrasound** testing reveals the positions of the baby and the placenta and provides an estimate of the baby's size and gestational age. Fetal heart monitors transmit any signals of fetal distress. Meconium (feces) in the amniotic fluid may indicate oxygen deprivation or other fetal **stress**. Oxygen deprivation can also be determined by testing the pH of a blood sample from the baby's scalp: a pH of 7.25 or higher is normal, between 7.2 and 7.25 is suspicious, and below 7.2 is a warning sign.

Prepping for a c-section involves inserting a catheter into the mother's bladder and an intravenous line into her arm. Leads for monitoring the mother's heart rate, heart rhythm, and blood pressure are attached. In the operating room, the mother is given anesthesia. Surgical drapes are placed over her body, except her head, blocking her direct view of the procedure. The patient's abdomen is washed with an antibacterial solution, and a portion of the pubic hair may be shaved.

Aftercare

Aftercare requires both the care given to any new mother after delivery and care for recovering from major surgery. The mother will be offered **pain** medication that does not interfere with breast feeding. She should be encouraged to walk around at 8 to 24 hours after surgery to stimulate circulation and bowel movements. The hospital stay is generally two to four days. Breast feeding is encouraged, in a position that prevents the baby from resting on the mother's incision. Mothers should limit climbing stairs to once a day and avoid lifting anything heavier than their baby. They should nap as often as the baby sleeps and arrange for help with housework, meals, and care of other children.

The aftereffects of a c-section vary, depending on the woman's age, physical fitness, and overall health. Following a cesarean, women commonly experience gas pains, incision pain, and uterine contractions (also common in vaginal delivery). Full recovery may be achieved in four to six weeks.

WWW.BOOKBAZ.IR

KEY TERMS

Breech presentation—A baby entering the birth canal buttocks or feet first rather than head first.

Cephalopelvic disproportion (CPD)—A condition in which the baby's head is too large to fit through the mother's pelvis.

Cesarean delivery on maternal request (CDMR)—The choice to have a cesarean delivery when it is not medically necessary.

Classical incision—A vertical incision of the uterus during cesarean delivery.

Dystocia—Failure to progress in labor, either because the cervix will not dilate (expand) further or (after full dilation) the baby's head does not descend through the mother's pelvis.

Hematoma—A collection of blood localized to an organ, tissue, or space in the body.

Hysterotomy—A surgical incision of the uterus.

Laparotomy—A surgical incision of the abdominal wall.

Low transverse incision—An incision made horizontally across the lower end of the uterus in cesarean delivery.

Placenta previa—A placenta that partially or totally covers the cervix, preventing vaginal delivery.

Placental abruption—Separation of the placenta from the uterine wall, cutting off blood flow to the fetus.

Preeclampsia—A pregnancy-related condition that causes high blood pressure and swelling.

Prolapsed cord—Pushing of the umbilical cord into the vagina ahead of the baby, cutting off its blood flow.

Transverse presentation—A baby laying sideways across the cervix rather than head first.

Trial of labor (TOL)—A purposeful attempt to deliver vaginally after a previous cesarean delivery.

Vaginal birth after cesarean (VBAC)—The option of having subsequent vaginal deliveries after a cesarean delivery.

Results

Cesarean sections almost always result in a healthy mother and infant. Of the hundreds of thousands of women in the United States who undergo c-sections each year, about 500 die from serious infections, hemorrhaging, or other complications of the procedure. Two-thirds of maternal deaths following cesareans are related to other conditions, including those that made the c-section necessary.

Risks

Because a c-section is a surgical procedure, it carries a greater risk of complications for both the mother and child than a vaginal delivery. Although the maternal death rate is less than 0.02%, that is four times the death rate associated with vaginal delivery. Other complications occur in fewer than 10% of cases.

The mother is at risk for increased bleeding from the two incisions, the placental attachment site, and possible damage to a uterine artery. A c-section may result in twice the blood loss of a vaginal delivery. Approximately 7% of women develop infections of the incision, urinary tract, or tissue lining the uterus. Less common is injury to the surrounding organs such as the bladder and bowel, occurring in approximately 0.1% of c-sections. There can also be complications from general anesthesia. Very rarely, a woman may develop a wound hematoma at the site of either incision or **blood clots** elsewhere in the body. The risk for developing **deep vein thrombosis** is three to five times higher with a cesarean than with vaginal delivery.

C-sections sometimes cause psychological distress that extends beyond hormonal mood swings and **postpartum depression** (the "baby blues"). Mothers may feel disappointment and a sense of failure at not experiencing a vaginal delivery. They may feel isolated if the father or birthing coach is not with them in the operating room or if an unfamiliar doctor delivers the baby. Women may feel that they have lost control over their labor and delivery with no opportunity to actively participate.

Chagas' disease

Definition

Chagas' disease, also called trypanosomiasis, is named after Dr. Carlos Chagas who first found the organism in the early 1900s. It involves damage to the nerves that control the heart, digestive and other organs, and eventually leads to damage to these organs. Worldwide, Chagas' disease affects between six and seven million persons annually, and kills 12,500 each year. Researchers believe that the parasite that causes the disease is only found in the Americas.

Description

When a person is infected with Chagas' disease, the parasite known as *Trypanosoma cruzi* first causes a

WWW.BOOKBAZ.IR

KEY TERMS

Achalasia—An esophageal disease of unknown cause, in which the lower sphincter or muscle is unable to relax normally, and leads to the accumulation of material within the esophagus.

Endoscopy—Exam using an endoscope (a thin flexible tube which uses a lens or miniature camera to view various areas of the gastrointestinal tract). When the procedure is performed to examine certain organs such as the bile ducts or pancreas, the organs are not viewed directly, but rather indirectly through the injection of x ray.

Parasite—An organism that lives on or in another and takes nourishment (food and fluids) from that organism.

Regurgitation—Flow of material back up the esophagus and into the throat or lungs.

mild, short-lived period of "acute" illness; then after a long period without symptoms, the effects of the infection begin to appear. The heart, esophagus, and colon are most frequently involved. These organs become unable to contract properly, and begin to stretch or dilate. About 20–30% of those infected will progress to the chronic form of the disease.

Causes and symptoms

T. cruzi is carried by insects or bugs known as reduviid or "kissing bugs." These insects are very common in Central and South America where they inhabit poorly constructed houses and huts. The insects deposit their waste material, exposing inhabitants to the parasites. The parasites then enter the body by way of a cut or via the eyes or mouth. *T. cruzi* can also be transmitted by blood **transfusion**, organ transplants, from a pregnant woman to her baby, by eating uncooked, contaminated food, or through **breastfeeding**. The reduviids, in turn, become infected with the parasite by biting infected animals and humans.

There are three phases related to infection:

- Acute phase lasts about two months, with non-specific symptoms of low grade fever, headache, fatigue, and enlarged liver or spleen.
- Indeterminate phase lasts 10–20 years, during which time no symptoms occur, but the parasites are reproducing in various organs.
- Chronic phase is the stage when symptoms related to damage of major organs (heart, esophagus, colon) begin.

In the chronic phase, irregularities of heart rhythm, **heart failure**, and **blood clots** cause weakness, **fainting**, and even sudden death.

Esophageal symptoms are related to difficulty with swallowing and chest **pain**. Because the esophagus does not empty properly, food regurgitates into the lungs causing **cough**, **bronchitis**, and repeated bouts of **pneumonia**. Inability to eat, weight loss, and **malnutrition** become a significant factor in affecting survival.

Involvement of the large intestine (colon) causes **constipation**, distention, and abdominal pain.

Diagnosis

The best way to diagnose acute infection is to identify the parasites in tissue or blood. Occasionally it is possible to culture the organism from infected tissue, but this process usually requires too much time to be of value. In the chronic phase, antibody levels can be measured. Currently, diagnosis may require repeated blood tests. Efforts to develop new, more accurate tests are ongoing.

Treatment

In most cases treatment of symptoms is all that is possible. Present medications can reduce the duration and severity of an acute infection, but are only 50% effective, at best, in eliminating the organisms.

Cardiac effects are managed with **pacemakers** and medications. Esophageal complications require either endoscopic or surgical methods to improve esophageal emptying, similar to those used to treat the disorder known as **achalasia**. Constipation is treated by increasing fiber and bulk **laxatives**, or removal of diseased portions of the colon.

Prognosis

Those patients with gastrointestinal complications often respond to some form of treatment. Cardiac problems are more difficult to treat, particularly since transplant would rekindle infection.

Prevention

Visitors traveling to areas of known infection should avoid staying in mud, adobe, or similar huts. Mosquito nets and insect repellents are useful in helping to avoid contact with the bugs. Blood screening is not always effective in many regions where infection is common. It is necessary to carefully screen people who have emigrated from Central and South America before they make blood donations.

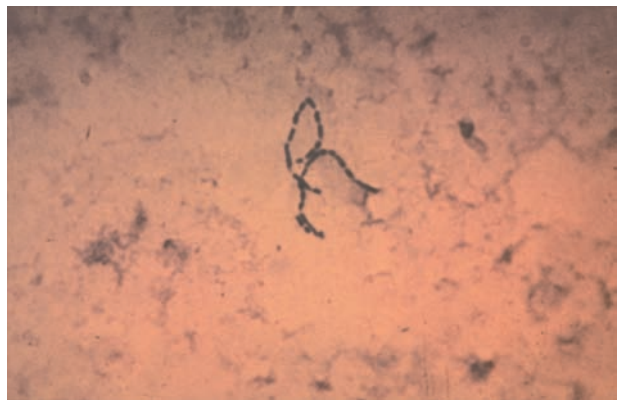
Chancroid

Definition

Chancroid is a sexually transmitted disease caused by a bacterial infection that is characterized by painful sores on the genitals.

Description

Chancroid is an infection of the genitals that is caused by the bacterium *Haemophilus ducreyi*. Chancroid is a sexually transmitted disease, which means that it is spread from person to person almost always by sexual contact. However, there have been a few cases in which healthcare providers have become infected through contact with infected patients.



A close-up view of a chancroid specimen. *(Custom Medical Stock Photo, Inc.)*

Common locations for chancroid sores (**ulcers**) in men are the shaft or head of the penis, foreskin, the groove behind the head of the penis, the opening of the penis, and the scrotum. In women, common locations are the labia majora (outer lips), labia minora (inner lips), perianal area (area around the anal opening), and inner thighs. It is rare for the ulcer(s) to be on the vaginal walls or cervix. In about 50% of the patients with chancroid, the infection spreads to either or both of the lymph nodes in the groin.

Demographics

Chancroid is most commonly found in developing and third world countries. In the United States, the most common cause of genital ulcers is **genital herpes**, followed by **syphilis**, and then chancroid. There are about 1,500 cases of chancroid in the United States per year and it occurred primarily in African Americans, Hispanic Americans, and Native Americans. There are occasional localized outbreaks of chancroid in the United States. In addition, the practice of exchanging sex for drugs has lead to a link between crack cocaine use and chancroid.

Even though the incidence of chancroid in the United States decreased in the 1990s, there is an alarming connection between chancroid and human **immunodeficiency** virus (HIV) infection. HIV causes **AIDS** (acquired immunodeficiency syndrome) and is easily spread from person to person through chancroid ulcers. Uncircumcised men with chancroid ulcers have a 48% risk of acquiring HIV from sexual contact. Women with chancroid ulcers are also at a greater risk of being infected with HIV during sexual contact. Genital ulcers seem to act as doorways for HIV to enter and exit.

WWW.BOOKBAZ.IR

Causes and symptoms

Haemophilus ducreyi is spread from person to person by vaginal, anal, and oral sexual contact. Uncircumcised men are about three times more likely than circumcised men to become infected following exposure to *Haemophilus ducreyi*. Having unprotected sex, exchanging sex for drugs, and having unprotected sex with a prostitute are other risk factors. Many cases of chancroid in the United States occur in persons who had traveled to countries where the disease is more common.

Chancroid occurs when *Haemophilus ducreyi* penetrates the skin through an injury, like a scratch or cut. Once past the skin surface, the warmth, moisture, and nutrients allow bacteria to grow rapidly. The first sign of chancroid is a small, red papule that occurs within three to seven days following exposure to the bacteria, but may take up to one month. Usually within one day, the papule becomes an ulcer. The chancroid ulcer is painful, bleeds easily, drains a grey or yellowish pus, and has sharply defined, ragged edges. They can vary in size from an eighth of an inch to two inches in diameter. Men usually have only one ulcer, but women often have four or more. Sometimes "kissing" ulcers occur when one ulcer spreads the bacterial infection to an opposite skin surface. For example, kissing ulcers can form on the lips of the labia majora. Alternatively, women may not have any external sores but may experience painful urination, intercourse, and/or bowel movements and may have a vaginal discharge or rectal bleeding.

Signs that the infection has spread to the lymph node appear about one week after the formation of the genital ulcer. Lymph nodes are small organs in the lymphatic system that filter waste materials from nearly every organ in the body. This lymph node infection is called "lymphadenitis" and the swollen, painful lymph node is called a "bubo." The bubo, which appears as a red, spherical lump, may burst through the skin, releasing a thick pus and forming another ulcer.

Diagnosis

Chancroid may be diagnosed and treated by urologists (urinary tract doctors for men), gynecologists (for women), and **infectious disease** specialists. Part of the diagnosis of chancroid involves ruling out genital herpes and syphilis because genital ulcers are also symptoms of these diseases. The appearance of these three diseases can be close enough to be confusing. However, the presence of a pus-filled lump in the groin of a patient with a genital ulcer is highly specific for chancroid.

KEY TERMS

Bubo—A tender, swollen lymph node in the groin that may follow a chancroid ulcer.

Groin—The region of the body that lies between the abdomen and the thighs.

For a clear-cut diagnosis of chancroid, *Haemophilus ducreyi* must be isolated from the ulcer. To do this, a sterile cotton swab is wiped over the ulcer to obtain a pus sample. In the laboratory, the sample is put into special media and placed in an incubator. *Haemophilus ducreyi* takes from two to five days to grow in the laboratory. In addition, the pus may be examined under the microscope to see which bacteria are in the ulcer. A sample of the pus may also be tested to see if the herpes virus is present. A blood sample will probably be taken from the patient's arm to test for the presence of antibodies to the bacteria that causes syphilis.

Treatment

The only treatment for chancroid is **antibiotics** given either once or for several days. Antibiotics taken by mouth for one to two weeks include erythromycin (E-Mycin, Ery-Tab), amoxicillin plus clavulanic acid (Augmentin), co-trimoxazole (Bactrim, Septra), or ciprofloxacin (Cipro). Antibiotics given in one dose include ceftriaxone (Rocephin), spectinomycin (Trobicin), co-trimoxazole, or ofloxacin (Floxin).

The ulcer(s) may be cleaned and soaked to reduce the swelling. Salt solution dressings may be applied to the ulcer(s) to reduce the spread of the bacteria and prevent additional ulcers. A serious infection of the foreskin may require **circumcision**. Pus would be removed from infected lymph nodes by using a needle and syringe. Very large buboes may require surgical drainage.

Prognosis

Without treatment, chancroid may either go away quickly or patients may experience the painful ulcers for many months. A complete cure is obtained with antibiotic treatment. Severe ulcers may cause permanent **scars**. Severe scarring of the foreskin may require circumcision. Urethral fistulas (abnormal passageways from the urine tube to the skin) may occur and requires corrective surgery.

Prevention

The best prevention for chancroid is to use a condom during sexual intercourse. Chancroid can also be prevented by abstinence (avoidance of any sexual contact) and by being in a monogamous relationship with a disease-free partner. To prevent the spread of chancroid, it is important that all sexual contacts of the patient are identified and treated.

Charcoal, activated

Definition

Activated charcoal is a fine black odorless and tasteless powder made from wood or other materials that have been exposed to high temperatures in an airless environment. The powder is treated (activated) with oxidizing gas or other chemicals to increase its ability to adsorb various substances. Activated charcoal is pure carbon that absorbs particles and gases in the body's digestive system.

Activated charcoal has been used since ancient times to cure various ailments and poisonings, and its healing effects have been documented since1550 B.C. by the Egyptians. In the 1980s, it was rediscovered as an oral treatment for **poisoning** and drug overdoses.

Description

Activated charcoal is not absorbed from the stomach or intestines and binds or adsorbs most drugs and poisons. Its most important use in humans is in treating **drug overdose** and poisoning. It is also sometimes used to treat **diarrhea** or excessive gas. It can be used to treat poisoned pets and animals. Other possible uses, in treating viruses, bacteria, bacterial toxic byproducts, snake venoms, and other substances, have not been supported by clinical studies. By adding water to the powder to make a paste, activated charcoal can be used as an external application to reduce **pain** and **itching** from **bites and stings**.

Poisons and drug overdoses

It is estimated that one million children accidentally overdose every year on medications, thinking they are candies, or eat, drink, or inhale poisonous household products. Infants and toddlers are at the greatest risk for accidental poisoning. Activated charcoal can absorb large quantities of poisons quickly in the intestines, is non-toxic, may be stored indefinitely, and can be conveniently administered at home. Charcoal binds irritating or toxic substances in the stomach and intestines, preventing their absorption, so they can be excreted in the stool. When poisoning is suspected, the local poison control center should always be contacted for instructions. They may recommend using activated charcoal, which should be available at home so that it can be immediately given to the poisoned child or pet. For severe poisoning, several doses of activated charcoal may be needed.

Activated charcoal is used in adults who have accidentally taken too much medication, or attempted **suicide** by intentionally taking a drug overdose.

Intestinal disorders

In the past, activated charcoal was a popular remedy for flatus (intestinal gas). But more recent studies have not shown its value. Other measures, like dietary changes or **biofeedback** training, are more effective in relieving patients' symptoms.

Charcoal has been used to treat other intestinal disorders like diarrhea, **constipation**, and cramps. There is little evidence to support these uses. Frequent use may decrease absorption of essential nutrients and cause constipation. So a laxative should be taken if several doses of charcoal are taken.

Other uses

Activated charcoal has been used to clean skin **wounds** and adsorb waste materials from the gastrointestinal tract. When used with other remedies such as aloe vera, acidophilus, and psyllium, charcoal helps keep symptoms of ulcerative **colitis** under control. While charcoal shows some anti-aging activity in rats, it is doubtful if it has the same effect in humans.

Apart from its medicinal applications, activated charcoal is used by biologists to cool cell suspensions; by **public health** physicians to filter disease organisms from drinking water; and by environmental scientists to remove organic pollutants from ocean sediments.

WWW.BOOKBAZ.IR

Recommended dosage

For poisoning

Activated charcoal is available without prescription. In cases of accidental poisoning or drug overdose, always call a poison control center for advice. If both syrup of **ipecac** and charcoal are recommended, ipecac should be given first to induce **vomiting**, and charcoal given only after vomiting stops. Activated charcoal may be mixed with a liquid and drunk, or put into a stomach tube. Activated charcoal is available as 1.1 oz (33 mL) and 0.5 oz (15 mL) containers as pre-mixed slurries, or as containers to which water or soda pop can be added. It is a good idea to keep activated charcoal at home for the immediate treatment of poisonings.

For acute poisoning, the dosage is as follows:

- infants (under 1 year of age): 1 g/kg
- children (1–12 years of age): 15–30 g or 1–2 g/kg with at least 8 oz of water
- adults: 30–100 g or 1–2 g/kg with at least 8 oz of water

For diarrhea

Charcoal can be taken as tablets or capsules with water, or sprinkled onto foods. The dosage for treatment of diarrhea in adults is 520–975 mg after each meal and up to 5 g per day.

Precautions

Parents should keep activated charcoal on hand for emergencies.

Charcoal should not be given together with syrup of ipecac as it will adsorb the ipecac. It should not be taken until after the vomiting from ipecac stops.

Some activated charcoal products contain sorbitol, a sweetener and laxative that can cause nausea, vomiting, and diarrhea. These products should not be used in infants.

Charcoal may interfere with the absorption of medications and nutrients such as **vitamins** or **minerals**. It should not be taken for at least two hours after other medications.

Charcoal should not be used to treat poisonings caused by lye or other corrosives, strong acids, or petroleum products like gasoline or cleaning fluids. In those cases, charcoal may cause treatment for the condition to be delayed. It is also not effective in lithium, cyanide, iron, ethanol, or methanol overdoses or poisonings.

KEY TERMS

Adsorption—The binding of a chemical (e.g., drug or poison) to a solid material such as activated charcoal or clay.

Antidote—A remedy to counteract unwanted effects from medications or poisons.

Flatus—Gas or air in the digestive tract.

Chocolate syrup, sherbet, or ice cream may improve the taste of charcoal, but they may prevent it from working properly.

Activated charcoal may produce abdominal pain or swelling, and can complicate intestinal bleeding or obstruction.

Charcoal may be less effective in people with slow digestion.

Charcoal should not be given for more than three or four days for treatment of diarrhea, as it may interfere with normal **nutrition**.

Charcoal should not be used in children under three years of age to treat diarrhea or gas.

Activated charcoal should be kept out of reach of children.

Side effects

Charcoal may cause constipation when taken for a drug overdose or accidental poisoning. A laxative should be taken after the crisis is over.

Activated charcoal normally causes stools to turn black.

Patients should consult a doctor if they have pain or swelling of the stomach.

Interactions

Chocolate syrup, ice cream, or sherbet mixed may prevent charcoal from working properly.

Charcot Marie Tooth disease

Definition

Charcot Marie Tooth disease (CMT) is the name of a group of inherited disorders of the nerves in the peripheral nervous system (nerves throughout the body that communicate motor and sensory information to and from the spinal cord) causing weakness and loss of sensation in the limbs.

Description

CMT is named for the three neurologists who first described the condition in the late 1800s. It is also known as hereditary motor and sensory neuropathy, and is sometimes called peroneal muscular atrophy, referring to the muscles in the leg that are often affected. The age of onset of CMT can vary anywhere from young childhood to the 50s or 60s. Symptoms typically begin by the age of 20. For reasons yet unknown, the severity in symptoms can also vary greatly, even among members of the same family.

Although CMT has been described for many years, it is only since the early 1990s that the genetic cause of many of the types of CMT have become known. Therefore, knowledge about CMT has increased dramatically within a short time.

The peripheral nerves

CMT affects the peripheral nerves, those groups of nerve cells carrying information to and from the spinal cord. CMT decreases the ability of these nerves to carry motor commands to muscles, especially those furthest from the spinal cord located in the feet and hands. As a result, the muscles connected to these nerves eventually weaken. CMT also affects the sensory nerves that carry information from the limbs to the brain. Therefore people with CMT also have sensory loss. This causes symptoms such as not being able to tell if something is hot or cold or difficulties with balance.

There are two parts of the nerve that can be affected in CMT. A nerve can be likened to an electrical wire, in which the wire part is the axon of the nerve and the insulation surrounding it is the myelin sheath. The job of the myelin is to help messages travel very fast through the nerves. CMT is usually classified depending on which part of the nerve is affected. People who have problems with the myelin have CMT type 1 and people who have abnormalities of the axon have CMT type 2.

Specialized testing of the nerves, called nerve conduction testing (NCV), can be performed to determine if a person has CMT1 or CMT2. These tests measure the speed at which messages travel through the nerves. In CMT1, the messages move too slowly, but in CMT2 the messages travel at the normal speed.

Demographics

CMT has been diagnosed in people from all over the world. It occurs in approximately one in 2,500 people, which is about the same incidence as **multiple sclerosis**. It is the most common type of inherited neurologic condition.

Causes and symptoms

CMT is caused by changes (mutations) in any one of a number of genes that carry the instructions to make the peripheral nerves. Genes contain the instructions for how the body grows and develops before and

WWW.BOOKBAZ.IR

after a person is born. There are probably at least 15 different genes that can cause CMT. However, many have not yet been identified.

CMT types 1 and 2 can be broken down into subtypes based upon the gene that is causing CMT. The subtypes are labeled by letters, so there is CMT1A, CMT1B, etc. Therefore, the gene with a mutation that causes CMT1A is different from the gene that causes CMT1B.

Types of CMT

CMT1A. The most common type of CMT is called CMT1A. It is caused by a mutation in a gene called peripheral myelin protein 22 (PMP22) located on chromosome 17. The job of this gene is to make a protein (PMP22) that makes up part of the myelin. In most people who have CMT, the mutation that causes the condition is a duplication (doubling) of the PMP22 gene. Instead of having two copies of the PMP22 gene (one on each chromosome) there are three copies. It is not known how this extra copy of the PMP22 gene causes the observed symptoms. A small percentage of people with CMT1A do not have a duplication of the PMP22 gene, but rather have a point mutation in the gene. A point mutation is like a typo in the gene that causes it to work incorrectly.

HEREDITARY NEUROPATHY WITH LIABILITY TO PRESSURE PALSIES (HNPP). HNPP is a condition that is also caused by a mutation in the PMP22 gene. The mutation is a deletion. Therefore, there is only one copy of the PMP22 gene instead of two. People who have HNPP may have some of the signs of CMT. However, they also have episodes where they develop weakness and problems with sensation after compression of certain pressure points such as the elbows or knee. Often these symptoms will resolve after a few days or weeks, but sometimes they are permanent.

CMT1B. Another type of CMT, called CMT1B, is caused by a mutation in a gene called myelin protein zero (MPZ) located on chromosome 1. The job of this gene is to make the layers of myelin stick together as they are wrapped around the axon. The mutations in this gene are point mutations because they involve a change (either deletion, substitution, or insertion) at one specific component of a gene.

CMTX. Another type of CMT, called CMTX, is usually considered a subtype of CMT1 because it affects the myelin, but it has a different type of inheritance than type 1 or type 2. In CMTX, the CMT–causing gene is located on the X chromosome and is called connexin 32 (Cx32). The job of this gene is to code for a class of protein called connexins that form tunnels between the layers of myelin.

CMT2. There are at least five different genes that can cause CMT type 2. Therefore, CMT2 has subtypes A, B, C, D, and E. As of early 2001, scientists have narrowed in on the location of most of the CMT2 causing genes. However, the specific genes and the mutations have not yet been found for most types. Very recently, the gene for CMT2E has been found. The gene is called neurofilament-light (NF-L). Because it has just been discovered, not much is known about how mutations in this gene cause CMT.

CMT3. In the past a condition called Dejerine-Sottas disease was referred to as CMT3. This is a severe type of CMT in which symptoms begin in infancy or early childhood. It is now known that this is not a separate type of CMT and in fact people who have onset in infancy or early childhood often have mutations in the PMP22 or MPZ genes.

CMT4. CMT4 is a rare type of CMT in which the nerve conduction tests have slow response results. However, it is classified differently from CMT1 because it is passed through families by a different pattern of inheritance. There are five different subtypes and each has only been described in a few families. The symptoms in CMT4 are often severe and other symptoms such as deafness may be present. There are three different genes that have been associated with CMT4 as of early 2001. They are called MTMR2, EGR2, and NDRG1. More research is required to understand how mutations in these genes cause CMT.

Inheritance

CMT1A and 1B, HNPP, and all of the subtypes of CMT2 have autosomal dominant inheritance. Autosomal refers to the first 22 pairs of chromosomes that are the same in males and females. Therefore, males and females are affected equally in these types. In a dominant condition, only one gene of a pair needs to have a mutation in order for a person to have symptoms of the condition. Therefore, anyone who has these types has a 50%, or one in two, chance of passing CMT on to each of their children. This chance is the same for each **pregnancy** and does not change based on previous children.

CMTX has X-linked inheritance. Since males only have one X chromosome, they only have one copy of the Cx32 gene. Thus, when a male has a mutation in his Cx32 gene, he will have CMT. However, females have two X chromosomes and therefore have two copies of the Cx32 gene. If they have a mutation in

one copy of their Cx32 genes, they will only have mild to moderate symptoms of CMT that may go unnoticed. This is because their normal copy of the Cx32 gene does make normal myelin.

Females pass on one or the other of their X chromosomes to their children—sons or daughters. If a woman with a Cx32 mutation passes her normal X chromosome, she will have an unaffected son or daughter who will not pass CMT on to his or her children. If the woman passes the chromosome with Cx32 mutation on she will have an affected son or daughter, although the daughter will be mildly affected or have no symptoms. Therefore, a woman with a Cx32 mutation has a 50%, or a one in two, chance of passing the mutation to her children: a son will be affected, and a daughter may only have mild symptoms.

When males pass on an X chromosome, they have a daughter. When they pass on a Y chromosome, they have a son. Since the Cx32 mutation is on the X chromosome, a man with CMTX will always pass the Cx32 mutation on to his daughters. However, when he has a son, he passes on the Y chromosome, and therefore the son will not be affected. Therefore, an affected male passes the Cx32 gene mutation on to all of his daughters, but to none of his sons.

CMT4 has autosomal recessive inheritance. Males and females are equally affected. In order for a person to have CMT4, they must have a mutation in both of their CMT–causing genes—one inherited from each parent. The parents of an affected person are called carriers. They have one normal copy of the gene and one copy with a mutation. Carriers do not have symptoms of CMT. Two carrier parents have a 25%, or one in four, chance of passing CMT on to *each* of their children.

The onset of symptoms is highly variable, even among members of the same family. Symptoms usually progress very slowly over a person's lifetime. The main problems caused by CMT are weakness and loss of sensation mainly in the feet and hands. The first symptoms are usually problems with the feet such as high arches and problems with walking and running. Tripping while walking and sprained ankles are common. Muscle loss in the feet and calves leads to "foot drop" where the foot does not lift high enough off the ground when walking. Complaints of cold legs are common, as are cramps in the legs, especially after **exercise**.

In many people, the fingers and hands eventually become affected. Muscle loss in the hands can make fine movements such as working buttons and zippers difficult. Some patients develop tremor in the upper limbs. Loss of sensation can cause problems such as numbness and the inability to feel if something is hot or cold. Most people with CMT remain able to walk throughout their lives.

Diagnosis

Diagnosis of CMT begins with a careful **neurological exam** to determine the extent and distribution of weakness. A thorough family history should be taken at this time to determine if other people in the family are affected. Testing may also be performed to rule out other causes of neuropathy.

A nerve conduction velocity test should be performed to measure how fast impulses travel through the nerves. This test may show characteristic features of CMT, but it is not diagnostic of CMT. Nerve conduction testing may be combined with **electromyography** (EMG), an electrical test of the muscles.

A nerve biopsy (removal of a small piece of the nerve) may be performed to look for changes characteristic of CMT. However, this testing is not diagnostic of CMT and is usually not necessary for making a diagnosis.

Definitive diagnosis of CMT is made only by **genetic testing**, usually performed by drawing a small amount of blood. Testing is available to detect mutations in PMP22, MPZ, Cx32, and EGR2. However, research is progressing rapidly and new testing is often made available every few months. All affected members of a family have the same type of CMT. Therefore once a mutation is found in one affected member, it is possible to test other members who may have symptoms or are at risk of developing CMT.

Prenatal diagnosis

Testing during pregnancy to determine whether an unborn child is affected is possible if genetic testing in a family has identified a specific CMT-causing mutation. This can be done after 10–12 weeks of pregnancy using a procedure called **chorionic villus sampling** (CVS). CVS involves removing a tiny piece of the placenta and examining the cells. Testing can also be done by **amniocentesis** after 16 weeks gestation by removing a small amount of the amniotic fluid surrounding the baby and analyzing the cells in the fluid. Each of these procedures has a small risk of **miscarriage** associated with it, and those who are interested in learning more should check with their doctor or genetic counselor. Couples interested in these options

WWW.BOOKBAZ.IR

KEY TERMS

Axon—Skinny, wire-like extension of nerve cells.

Myelin—A fatty sheath surrounding nerves in the peripheral nervous system, which helps them conduct impulses more quickly.

Nerve conduction testing—Procedure that measures the speed at which impulses move through the nerves.

Neuropathy—A condition caused by nerve damage. Major symptoms include weakness, numbness, paralysis, or pain in the affected area.

Peripheral nerves—Nerves throughout the body that carry information to and from the spinal cord.

should obtain **genetic counseling** to carefully explore all of the benefits and limitations of these procedures.

Treatment

There is no cure for CMT. However, physical and **occupational therapy** are an important part of CMT treatment. **Physical therapy** is used to preserve range of motion and minimize deformity caused by muscle shortening, or contracture. Braces are sometimes used to improve control of the lower extremities that can help tremendously with balance. After wearing braces, people often find that they have more energy because they are using less energy to focus on their walking. Occupational therapy is used to provide devices and techniques that can assist tasks such as dressing, feeding, writing, and other routine activities of daily life. Voice-activated software can also help people who have problems with fine motor control.

It is very important that people with CMT avoid injury that causes them to be immobile for long periods of time. It is often difficult for people with CMT to return to their original strength after injury.

There is a long list of medications that should be avoided if possible by people diagnosed with CMT such as hydralazine (Apresoline); megadoses of **vitamin A**, B_6, and D; Taxol; and large intravenous doses of penicillin. Complete lists are available from the CMT support groups. People considering taking any of these medications should weigh the risks and benefits with their physician.

Prognosis

The symptoms of CMT usually progress slowly over many years, but do not usually shorten life expectancy. The majority of people with CMT do not need to use a wheelchair during their lifetime. Most people with CMT are able to lead full and productive lives despite their physical challenges.

Charcot's joints

Definition

Charcot's joints is a progressive degenerative disease of the joints caused by nerve damage resulting in the loss of ability to feel **pain** in the joint and instability of the joint.

Description

Charcot's joints, also called neuropathic joint disease, is the result of two conditions present in the joint. The first factor is the inability to feel pain in the joint

due to nerve damage. The second factor is that injuries to the joint go unnoticed leading to instability and making the joint more susceptible to further injury. Repeated small injuries, strains, and even **fractures** can go unnoticed until finally the joint is permanently destroyed. Loss of the protective sensation of pain is what leads to the disintegration of the joint and often leads to deformity in the joint.

Although this condition can affect any joint, the knee is the joint most commonly involved. In individuals with **diabetes mellitus**, the foot is most commonly affected. The disease can involve only one joint or it may affect two or three joints. More than three affected joints is very rare. In all cases, the specific joint(s) affected depends on the location of the nerve damage.

Causes and symptoms

Many diseases and injuries can interfere with the ability to feel pain. Conditions such as diabetes mellitus, spinal injuries and diseases, **alcoholism**, and even **syphilis** can all lead to a loss of the ability to feel pain in some areas. Lack of pain sensation may also be congenital.

The symptoms of Charcot's joints can go unnoticed for some time and may be confused with **osteoarthritis** in the beginning. Swelling and stiffness in a joint without the expected pain, or with less pain than would be expected, are the primary symptoms of this condition. As the condition progresses, however, the joint can become very painful due to fluid build-up and bony growths.

Diagnosis

Charcot's joints is suspected when a person with a disease that impairs pain sensation exhibits painless swelling and/or stiffness in a joint. Standard x rays will show damage to the joint, and may also show abnormal bone growth and **calcium** deposits. Floating bone fragments from previous injuries may also be visible.

Treatment

In the early stages of Charcot's joints, braces to stabilize the joints can help stop or minimize the damage. When the disease has progressed beyond braces, surgery can sometimes repair the joint. If the damage is extensive, an artificial joint may be necessary.

Prognosis

Treatment of the disease causing loss of pain perception may help to slow the damage to the joints.

Prevention

Preventing or effectively managing the underlying disease can slow or in some cases reverse joint damage, but the condition cannot be prevented.

Chelation therapy

Definition

Chelation therapy is an intravenous treatment designed to bind heavy metals in the body in order to treat heavy metal toxicity. Proponents claim it also treats **coronary artery disease** and other illnesses that may be linked to damage from free radicals (reactive molecules).

Purpose

The benefits of EDTA chelation for the treatment of **lead poisoning** and excessively high **calcium** levels are undisputed. The claims of benefits for those suffering from atherosclerosis, coronary artery disease, and other degenerative diseases are more difficult to prove. Reported uses for chelation therapy include treatment of **angina**, **gangrene**, arthritis, **multiple sclerosis**, Parkinson's disease, **psoriasis**, and Alzheimer's disease. Improvement is also claimed for people experiencing diminished sight, hearing, smell, coordination, and sexual potency.

Description

Origins

The term chelation is from the Greek root word "chele," meaning "claw." Chelating agents, most commonly diamine tetraacetic acid (EDTA), were originally designed for industrial applications in the early 1900s. It was not until the World War II era that the potential for medical therapy was realized. The initial intent was to develop antidotes to poison gas and

WWW.BOOKBAZ.IR

radioactive contaminants. The need for widespread therapy of this nature did not materialize, but more practical uses were found for chelation. During the following decade, EDTA chelation therapy became standard treatment for people suffering from lead **poisoning**. Patients who had received this treatment claimed to have other health improvements that could not be attributed to the lead removal only. Especially notable were comments from those who had previously suffered from **intermittent claudication** and angina. They reported suffering less **pain** and **fatigue**, with improved endurance, after chelation therapy. These reports stimulated further interest in the potential benefits of chelation therapy for people suffering from atherosclerosis and coronary artery disease.

If the preparatory examination suggests that there is a condition that could be improved by chelation therapy, and there is no health reason why it shouldn't be used, then the treatment can begin. The patient is generally taken to a comfortable treatment area, sometimes in a group location, and an intravenous line is started. A solution of EDTA together with **vitamins** and **minerals** tailored for the individual patient is given. Most treatments take three to four hours, as the infusion must be given slowly in order to be safe. The number of recommended treatments is usually between 20 and 40. They are given one to three times a week. Maintenance treatments can then be given at the rate of once or twice a month. Maximum benefits are reportedly attained after approximately three months after a treatment series. The cost of therapy is considerable, but it is a fraction of the cost of an expensive medical procedure like cardiac bypass surgery. Intravenous vitamin C and mercury chelation therapies are also offered.

Preparations

A candidate for chelation therapy should initially have a thorough history and physical to define the type and extent of clinical problems. Laboratory tests will be done to determine whether there are any conditions present that would prevent the use of chelation. Patients who have preexisting **hypocalcemia**, poor liver or kidney function, **congestive heart failure**, **hypoglycemia**, **tuberculosis**, clotting problems, or potentially allergic conditions are at higher risk for complications from chelation therapy. A Doppler **ultrasound** may be performed to determine the adequacy of blood flow in different regions of the body.

Precautions

It is important for people who receive chelation therapy to work with medical personnel who are experienced in the use of this treatment. Treatment should not be undertaken before a good physical, lifestyle evaluation, history, and any laboratory tests necessary are performed. The staff must be forthcoming about test results and should answer any questions the patient may have. Evaluation and treatment should be individualized and involve assessment of kidney function before each treatment with chelation, since the metals bound by the EDTA are excreted through the kidneys.

Although EDTA binds harmful, toxic metals like mercury, lead, and cadmium, it also binds some essential nutrients of the body, such as copper, iron, calcium, zinc, and magnesium. Large amounts of zinc are lost during chelation. Zinc deficiency can cause impaired immune function and other harmful effects. Supplements of zinc are generally given to patients undergoing chelation, but it is not known whether this is adequate to prevent deficiency. Also, chelation therapy does not replace proper **nutrition**, **exercise**, and appropriate medications or surgery for specific diseases or conditions.

Side effects

Side effects of chelation therapy are reportedly unusual, but are occasionally serious. Mild reactions may include, but are not limited to, local irritation at the infusion site, skin reactions, nausea, **headache**, **dizziness**, hypoglycemia, **fever**, leg cramps, or loose bowel movements. Some of the more serious complications reported have included hypocalcemia, kidney damage, decreased clotting ability, anemia, bone marrow damage, insulin **shock**, **thrombophlebitis** with **embolism**, and even rare deaths. However, some doctors feel that the latter groups of complications occurred before the safer method currently used for chelation therapy was developed.

Research and general acceptance

EDTA chelation is a highly controversial therapy. The treatment is approved by the United States Food and Drug Administration (FDA) for lead poisoning and seriously high calcium levels. However, for the treatment of atherosclerotic **heart disease**, EDTA chelation therapy is not endorsed by the American Heart Association (AHA), the FDA, the National Institutes of Health (NIH), or the American College of Cardiology. The AHA reports that there are no adequate, controlled, published scientific studies using currently approved scientific methods to support this therapy for the treatment of coronary artery disease. However,

KEY TERMS

Angina—Chest pain caused by reduced oxygen to the heart.

Atherosclerosis—Arterial disease characterized by fatty deposits on inner arterial walls.

Hypocalcemia—Low blood calcium.

Hypoglycemia—Low blood sugar.

Intermittent claudication—Leg pain and weakness caused by walking.

Thrombophlebitis—Inflammation of a vein together with clot formation.

a pooled analysis from the results of over 70 studies showed positive results in all but one.

Chemistry screen

Definition

A chemistry screen is a blood test done to check for normal levels of various blood elements. A chemistry screen measures levels of the following blood parameters: electrolytes, specific proteins, lipids, sugar, enzymes associated with specific organs, blood gases, waste products, and other blood elements.

Purpose

There are many different reasons a physician may order a blood chemistry screen. A chemistry screen may be done as part of a routine examination to assess normal body function or a routine blood laboratory workup prior to surgery. Chemistry screens are used to identify potential disease states present in a patient, to monitor the progression of a patient's disease, to monitor disease treatment or recurrence of a disease, to observe levels of certain prescription medicines, or to assess the effects of prescription medicines that may be harmful.

Description

A chemistry screen is prescribed by a physician. It is a routine test that is run before a surgical procedure. A nurse often draws the blood sample from the patient. The blood sample is then sent to a specific hospital laboratory that tests the blood. The results of the chemistry screen are then sent to the physician for review.

Chemistry screens provide information on the quantity of specific chemical parameters in the blood. The patient's blood levels are listed along with a reference range of values for each component. The reference range indicates what the normal range of values is, from low to high. The chemistry screen compares the patient's blood levels to the reference range, and flags the patient's blood values as falling outside of the normal range when necessary. If the patient's values fall within the reference range, the value is considered normal. If the patient's value is higher or lower than the reference range, the physician then evaluates the results and follows a proper course of action. Whether or not a patient's blood chemistry screen demonstrates normal results can help determine whether a patient has a condition requiring surgery, or whether they are fit enough for a particular surgical procedure to be successful.

Chemistry screens can test for many different blood parameters, and can be customized by the physician to fit a particular patient's medical needs. When chemistry screens are customized, the physician merely indicates on the prescription that parameters not usually included in a standardized screen are to be included. Standardized forms of chemistry screens often used in the hospital include the Chem-6, Chem-7, Chem-12, and Chem-20, which measure 6, 7, 12, and 20 different blood components, respectively. The type of chemistry screen chosen by the physician is determined by the reason for the

WWW.BOOKBAZ.IR

chemistry screen, any diseases the patient has, and specific medical symptoms the patient is experiencing that need to be explored via the results of the screen. The Chem-20 is the most thorough, and includes all the parameters measured in the smaller screens with some additions.

The Chem-20 chemistry screen

The blood parameters measured in the Chem-20 chemistry screen are:

- alanine aminotransferase (ALT)
- albumin
- alkaline phosphatase (ALP)
- aspartate aminotransferase (AST)
- blood urea nitrogen (BUN)
- calcium
- carbon dioxide
- chloride
- conjugated/direct bilirubin
- creatinine
- gamma-glutamyl transpeptidase (GGT)
- glucose
- lactate dehydrogenase (LDH)
- phosphate
- potassium
- sodium
- total bilirubin
- total cholesterol
- total protein
- uric acid

The blood components measured in the chemistry screen may be affected by various disease or nutritional states. A physician can learn much about the health condition of a patient by interpreting the results of a chemistry screen. The overall picture of health presented by the combined measurements in the chemistry screen are more informative than any one value alone.

Blood parameters measured in a chemistry screen

Albumin is a blood component made in the liver. Albumin binds to and carries certain substances in the blood, including some medications. It is important for keeping the proper amount of fluid within blood vessels, tissue growth, and healing. Albumin is measured to help assess liver and kidney function, as well as nutritional state.

Blood urea nitrogen tests how well the kidneys are functioning to remove waste from the body for excretion in the urine. Creatinine is another parameter measured to help assess kidney function. The ratio of the amount of BUN and creatinine present in the blood provides a more detailed picture of kidney function than either measurement alone. Uric acid is an indicator of kidney function in removing waste from the blood.

ALT, ALP, AST, GGT, and LDH are all enzymes associated with the liver whose levels help assess liver function and whether the liver is damaged. In addition to the liver, ALP is associated with the kidney, bones, and placenta. LDH is also associated with many different organs including the heart, brain, and skeletal muscle and is released with tissue damage. Bilirubin is a breakdown product of red blood cells that is taken up from the blood by the liver, altered, and secreted through the bile into the digestive tract where it is partially excreted in feces. Measurements involving bilirubin assess how well the liver and associated biliary tract is functioning.

Electrolytes such as potassium, sodium, and chloride are measured in chemistry screens. Electrolytes are minerals found naturally in the body. They are necessary to keep a balance in body fluids and to maintain normal body functions such as heart rhythm, muscle contraction, and brain function. Electrolyte imbalances can be caused by various disease states, including kidney disease. Calcium and phosphate levels may also be affected by kidney function, parathyroid disorders, and certain bone diseases. Both chloride and bicarbonate levels are indicative of acid base disorders and the ability of the blood to buffer acid and base to determine the pH value.

Cholesterol is measured to assess the level of fatty substances in the blood that affect the arteries and the heart. Glucose levels are potential indicators of liver function, pancreatic function, and the body's ability to utilize sugar for energy. Carbon dioxide gas levels in the blood assess the function of both the lungs and the kidneys. Each component of the chemistry screen can be affected in distinct ways by many different disease states. Interpreting the results of the chemistry screen requires much training and experience.

Preparation

Some parameters of the chemistry screen may require a period of fasting from all food and drink (except water) before the test. Patients should also avoid high fat foods or alcohol the night before the test. Since some medications may affect the results of

KEY TERMS

Bile—Green fluid secreted by the liver, stored in the gallbladder, and released into the digestive tract. Bile aids in the digestion of fat.

Biliary tract—The passages that allow the flow of bile from the gallbladder to the intestines.

Parathyroid gland—Small endocrine glands that release hormones to regulate calcium and phosphorous.

pH—A value that indicates the balance between acid and base in a given substance.

Phlebitis—Inflammation of a vein.

the chemistry screen, it is critical that the physician take into account all prescription medications, nonprescription medications, herbal, and nutritional supplements that the patient is taking before running the chemistry screen. Some people may have slightly high or low values as their normal level. Age and gender may also affect the results in predictable patterns.

Risks

There is very little risk associated with having blood drawn for a chemistry screen. Most people have no side effects; some may get a small bruise where the syringe was inserted. With any blood draw there is a small chance that the area around the punctured vein may develop phlebitis, the inflammation of a vein. Phlebitis may also involve a bacterial infection if the site of the blood draw was not appropriately cleaned before the needle was inserted. Phlebitis can be locally painful but usually resolves in a short period of time.

Additionally, patients with disorders involving the inability of the blood to form normal blood clots should discuss their condition and their medications with the physician before the blood draw and chemistry screen is done.

Maria Basile, PhD

Chemobrasion *see* **Skin resurfacing**

Chemonucleolysis

Definition

Chemonucleolysis is a medical procedure that involves the dissolving of the gelatinous cushioning material in an intervertebral disk by the injection of an enzyme such as chymopapain.

Purpose

Between each vertebra lies a disk of cushioning material that keeps the spinal bones from rubbing together and absorbs some of the **shock** to the spine from body movements. In the center of the disk is soft, gelatinous material called the nucleus pulposus (NP). The NP is surrounded by a tough fibrous coating. Sometimes when the back is injured, this coating can weaken and bulge or tear to allow the NP to ooze out. When this happens, it is called a herniated nucleus pulposus (HNP), or—in common language—a **herniated disk**.

When the disk bulges or herniates, it can put pressure on nerves which originate in the spinal column, and go to other parts of the body. This causes lower back **pain**, and/or pain to the hips, legs, arms, shoulders, and neck, depending on the location of the herniated disk. Chemonucleolysis uses chymopapain, an enzyme derived from papyrus, to dissolve the disk material that has been displaced because of injury. Herniated disks are the cause of only a small proportion of cases of lower back pain, and chemonucleolysis is appropriate for only some cases of HNP.

Chemonucleolysis is a conservative alternative to disk surgery. There are three types of disk injuries. A protruded disk is one that is intact but bulging. In an extruded disk, the fibrous wrapper has torn and the

WWW.BOOKBAZ.IR

NP has oozed out, but is still connected to the disk. In a sequestered disk, a fragment of the NP has broken loose from the disk and is free in the spinal canal. Chemonucleolysis is effective on protruded and extruded disks, but not on sequestered disk injuries. In the United States, chymopapain chemonucleolysis is approved only for use in the lumbar (lower) spine. In other countries, it has also been used successfully to treat cervical (upper spine) hernias.

Other indications that a patient is a good candidate for chemonucleolysis instead of surgery include:

- the patient is 18–50 years of age
- leg pain is worse than lower back pain
- other conservative treatments have failed
- The spot where the herniated disk presses on the nerve has been pinpointed by myelography, computed tomography scan (CT scan), or magnetic resonance imaging (MRI)
- the patient wishes to avoid surgery

Description

A small gauge needle is placed in the center of the affected disk. Chymopapain is introduced into the disk. The patient needs to remain still.

Precautions

There are some situations in which chemonucleolysis should not be performed. Chymopapain is derived from the papaya. About 0.3% of patients are allergic to chymopapain and go into life-threatening shock when exposed to the enzyme. Chemonucleolysis should not be performed on patients allergic to chymopapain or papaya. It also should not be done:

- when the patient is pregnant
- if the disk is sequestered
- if the patient has had several failed back operations
- if a spinal cord tumor is present
- if the patient has a neurological disease such as multiple sclerosis

Other conditions may affect the appropriateness of chemonucleolysis, including **hypertension**, **obesity**, diabetes, and a family history of **stroke**.

Preparation

Patients will need tests such as a myelogram or CT scan to pinpoint the herniated disk. Some doctors medicate the patient 24 hours prior to the operation in order to decrease the chances of post-operative lower back stiffness.

KEY TERMS

Chymopapain—An enzyme from the milky white fluid of the papaya, used for medical purposes in chemonucleolysis.

Myelography—An x-ray test that evaluates the subarachnoid space of the spine.

Nucleus pulposus (NP)—An elastic, pulpy mass in the center of each vertebral disk.

Aftercare

Patients may feel lower back stiffness, which goes away in few weeks. Heavy lifting and sports activities should be avoided for at least three months.

Results

Many patients feel immediate relief from pain, but, in about 30% of patients, maximal relief takes six weeks. The long term (seven to 20 years) success rate averages about 75%, which is comparable to the success rate for conventional surgery.

Risks

The greatest risk is that the patient may be allergic to chymopapain. The death rate for chemonucleolysis is only 0.02%. Complications overall are five to 10 times less than with conventional surgery, and the failure rate is roughly comparable to the failure rate in conventional disk surgery.

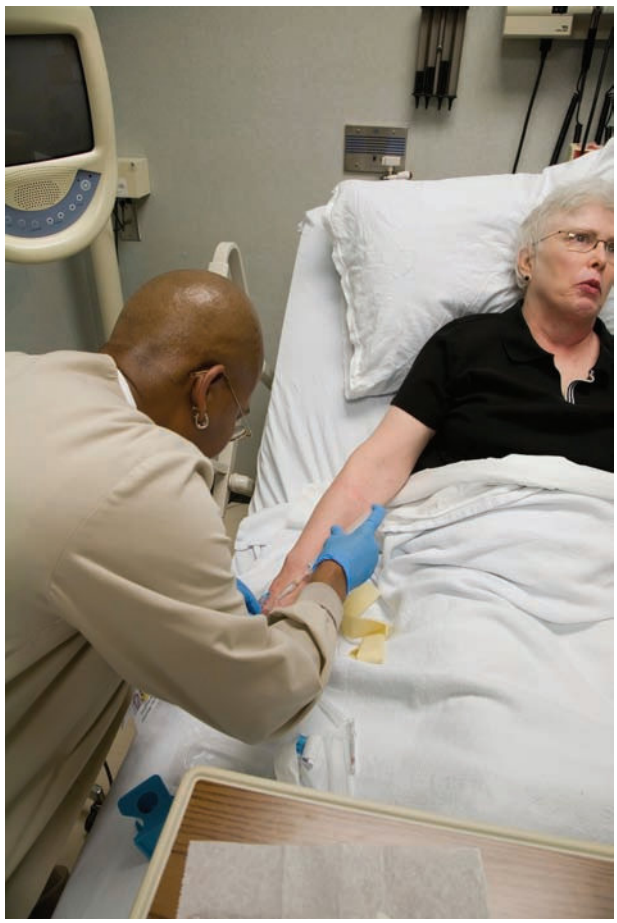
Chemotherapy

Definition

Chemotherapy is treatment of cancer with **anticancer drugs**.



Woman undergoing a clinical trial to test a new chemotherapy treatment. *(© Jim West/Alamy.)*

Purpose

The main purpose of chemotherapy is to kill cancer cells. It usually is used to treat patients with cancer that has spread from the place in the body where it started (metastasized). Chemotherapy destroys cancer cells anywhere in the body. It even kills cells that have broken off from the main tumor and traveled through the blood or lymph systems to other parts of the body.

Chemotherapy can cure some types of cancer. In some cases, it is used to slow the growth of cancer cells or to keep the cancer from spreading to other parts of the body. When a cancer has been removed by surgery, chemotherapy may be used to keep the cancer from coming back (adjuvant therapy). Chemotherapy also can ease the symptoms of cancer, helping some patients have a better quality of life.

Description

Numerous chemotherapy drugs are currently available to treat cancer and many more are being tested for their ability to destroy cancer cells. Most chemotherapy drugs interfere with a cell's ability to grow or multiply. Although these drugs affect all cells in the body, many useful treatments are most effective against rapidly growing cells. Cancer cells of some tumor types grow more quickly than most other body cells. Other cells that grow fast are cells of the bone marrow that produce blood cells, cells in the stomach and intestines, and cells of the hair follicles. Therefore, the most common side effects of chemotherapy are linked to the treatment's effects on other fast growing cells.

Types of chemotherapy drugs

Chemotherapy drugs are classified based on how they work. Drugs that kill cancer cells in a specific part of the cell cycle are called cell cycle specific agents:

- Antimetabolites interfere with the production of DNA and keep cells from growing and multiplying. An example of an antimetabolite is 5-fluorouracil (5-FU).
- Vinca alkaloids prevent cells from dividing normally. Vinblastine and vincristine are plant alkaloids obtained from the periwinkle plant.
- Epipodophyllotoxins work by damaging the cell prior to cell division. Drugs such as etoposide and teniposide are categorized as epipodophyllotoxins.
- Taxanes cause cell death by interfering with actions critical to cell function and by arresting cell division. Paclitaxel (Taxol) and docetaxel (Taxotere) are members of this drug group.
- Epothilones work similarly to the taxanes in causing cell death. Ixabepilone (Ixempra) is classified as an epothilone.
- Camptothecins such as toptecan (Hycamtin) and irinotecan (Camptosar) work in the synthesis phase of the cell cycle to cause cell death.
- Miscellanous agents include L-asparinginase (ELSPAR), which exerts its activity in the first growth phase of cell division, and bleomycin (Blenoxane), which works in the second growth phase to arrest cancer cell division.

Chemotherapy drug categories classified as having cell cycle nonspecific mechanisms of action include:

- alkylating drugs that kill cancer cells by directly attacking DNA, the genetic material of the genes. Cyclophosphamide is an alkylating drug.
- antitumor antibiotics that are made from natural substances such as fungi in the soil. They interfere with important cell functions, including production

WWW.BOOKBAZ.IR

of DNA and cell proteins. Doxorubicin (Adriamycin) and thiotepa belong to this group of chemotherapy drugs.

Combination chemotherapy

Chemotherapy usually is given in addition to other cancer treatments, such as surgery and **radiation therapy**. When given with other treatments, it is called adjuvant chemotherapy. An oncologist decides which chemotherapy drug or combination of drugs will work best for each patient. The use of two or more chemotherapy drugs together often works better than a single drug for treating cancer. This is called combination chemotherapy. Scientific studies of different drug combinations (clinical trials) help doctors learn which combinations work best for each type of cancer.

How chemotherapy is given

Chemotherapy is administered in different ways, depending on the drugs to be given and the type of cancer. Doctors decide the dose of chemotherapy drugs considering many factors, among them being the patient's height and weight.

Oral chemotherapy is given by mouth in the form a pill, capsule, or liquid. This is the easiest method and can usually be done at home.

Intravenous (IV) chemotherapy is injected into a vein. A small needle is inserted into a vein on the hand or lower arm. The needle usually is attached to a small tube called a catheter, which delivers the drug from an IV bag or bottle.

Intramuscular (IM) chemotherapy is injected into a muscle. Chemotherapy given by intramuscular injection is absorbed into the blood more slowly than IV chemotherapy. Because of this, the effects of IM chemotherapy may last longer than chemotherapy given intravenously. Chemotherapy also may be injected subcutaneously (SQ or SC), which means under the skin. Because of the toxic effects of many chemotherapy drugs on tissue, intramuscular and subcutaneous administration of these drugs is not common. Injection of chemotherapy directly into the cancer is called intralesional (IL) injection.

Chemotherapy may be given by a catheter or port temporarily inserted into a central, large vein or body cavity. A port is a small reservoir or container that is placed in a vein or under the skin in the area where the drug will be given. These methods eliminate the need for repeated injections and may allow patients to spend less time in the hospital while receiving chemotherapy. Intraperitoneal (IP) chemotherapy is administered into the abdominal cavity through a catheter or port. Chemotherapy given by catheter or port into the spinal fluid is called intrathecal (IT) administration. Catheters and ports may be placed in the chest cavity, bladder, or pelvis, depending on the location of the cancer to be treated.

Topical chemotherapy is given as a cream or ointment applied directly to the cancer. This method is more common in treatment of certain types of **skin cancer**.

Treatment location and schedule

Patients may receive chemotherapy in the doctor's office, or as an inpatient or outpatient at the hospital.

How often and how long chemotherapy is given depends on the type of cancer, how patients respond to the drugs, patients' health and ability to tolerate the drugs, and the types of drugs given. Chemotherapy administration may take only a few minutes or may last as long as several hours. Chemotherapy may be given daily, weekly, or monthly. A rest period may follow a course of treatment before the next course begins. In combination chemotherapy, more than one drug may be given at a time, or they may be given alternately, one following the other.

Precautions

There are many different types of chemotherapy drugs. Oncologists, doctors who specialize in treating cancer, determine which drugs are best suited for each patient. This decision is based on the type of cancer, the patient's age and health, and other drugs the patient is taking. Some patients should not be treated with certain chemotherapy drugs. Age and other conditions may affect the drugs with which a person may be treated. **Heart disease**, **kidney disease**, and diabetes are conditions that may limit the choice of treatment drugs.

Preparation

A number of medical tests are done before chemotherapy is started. The oncologist will determine how much the cancer has spread from the results of x rays and other imaging tests and from samples of the tumor taken during surgery or biopsy.

Blood tests give the doctor important information about the function of the blood cells and levels of chemicals in the blood. A **complete blood count** (CBC) is commonly done before and regularly during treatment. The CBC shows the numbers of white

KEY TERMS

Adjuvant therapy—Treatment given after surgery or radiation therapy to prevent the cancer from coming back.

Alkaloid—A type of chemical commonly found in plants and often having medicinal properties.

Alykylating drug—A drug that kills cells by directly damaging DNA.

Antiemetic—A medicine that helps control nausea; also called an anti-nausea drug.

Antimetabolite—A drug that interferes with a cell's growth or ability to multiply.

Platelets—Blood cells that function in blood clotting.

blood cells, red blood cells, and platelets in the blood. Because chemotherapy affects the bone marrow, where blood cells are made, levels of these cells often drop during chemotherapy. The white blood cells and platelets are most likely to be affected by chemotherapy. A drop in the **white blood cell count** means the immune system cannot function properly. Low levels of platelets can cause a patient to bleed easily from a cut or other wound. A low red blood cell count can lead to anemia (deficiency of red blood cells) and **fatigue**.

When a chemotherapy treatment takes a long time, the patient may prepare for it by wearing comfortable clothes. Bringing a book to read or a tape to listen to may help pass the time and ease the **stress** of receiving chemotherapy. Some patients bring a friend or family member to provide company and support during treatment.

Sometimes, patients taking chemotherapy drugs known to cause nausea are given medications called anti-emetics before chemotherapy is administered. Anti-emetic drugs help to lessen feelings of nausea. Two anti-nausea medications that may be used are Kytril and Zofran.

Other ways to prepare for chemotherapy and help lessen nausea are:

- regularly eating nutritious foods and drinking lots of fluids
- eating and drinking normally until about two hours before chemotherapy
- eating high carbohydrate, low-fat foods and avoiding spicy foods

Aftercare

Tips for helping to control side effects after chemotherapy include:

- following any instructions given by the doctor or nurse
- taking all prescribed antinausea medications
- eating small amounts of bland foods
- drinking lots of fluids
- getting plenty of rest

Some patients find it helps to breathe fresh air or get mild **exercise**, such as taking a walk.

Results

The main goal of chemotherapy is to cure cancer. Many cancers are cured by chemotherapy. It may be used in combination with surgery and/or radiation therapy to keep a cancer from spreading to other parts of the body. Some widespread, fast-growing cancers are more difficult to treat. In these cases, chemotherapy may slow the growth of the cancer cells.

Doctors can tell if the chemotherapy is working by the results of medical tests. **Physical examination**, blood tests, and x rays are all used to check the effects of treatment on the cancer.

The possible outcomes of chemotherapy are:

- Complete remission or response. The cancer completely disappears. The course of chemotherapy is completed and the patient is tested regularly for a recurrence.
- Partial remission or response. The cancer shrinks in size but does not disappear. The same chemotherapy may be continued or a different combination of drugs may be tried.
- Stabilization. The cancer does not grow or shrink. Other therapy options may be explored. A tumor may remain stabilized for many years.
- Progression. The cancer continues to grow. Other therapy options may be explored.
- A secondary malignancy may develop as a result of being treated with some chemotherapy agents, and that second cancer may need additional chemotherapy or other treatment.

Risks

Chemotherapy drugs are toxic to normal cells as well as cancer cells. A dose that will destroy cancer cells will probably cause damage to some normal cells. Doctors adjust doses to do the least amount of harm

WWW.BOOKBAZ.IR

possible to normal cells. Some patients feel few or no side effects, and others may have more serious side effects. In some cases, a dose adjustment may be required to reduce or stop a side effect.

Some chemotherapy drugs have more side effects than others. The most common side effects are:

- nausea and vomiting
- loss of appetite
- hair loss
- anemia and fatigue
- infection
- easy bleeding or bruising
- sores in the mouth and throat
- neuropathy and other damage to the nervous system
- kidney damage

Nausea and vomiting are common, but can usually be controlled by **antinausea drugs**, drinking fluids, and avoiding spicy foods. Loss of appetite may be due to nausea or the stress of undergoing cancer treatment.

Some chemotherapy drugs cause hair loss, but it is almost always temporary.

Low blood cell counts caused by the effect of chemotherapy on the bone marrow can lead to anemia, infections, and easy bleeding and bruising. Patients with anemia have too few red blood cells to deliver oxygen and nutrients to the body's tissues. Anemic patients feel tired and weak. If red blood cell levels fall too low, a blood **transfusion** may be given.

Patients receiving chemotherapy are more likely to get infections. This happens because their infection-fighting white blood cells are reduced. It is important to take measures to avoid getting infections. When the white blood cell count drops too low, the doctor may prescribe medications called colony stimulating factors that help white blood cells grow.

Platelets are blood cells that make the blood clot. When patients do not have enough platelets, they may bleed or bruise easily, even from small injuries. Patients with low blood platelets should take precautions to avoid injuries. Medicines such as **aspirin** and other **pain** relievers can affect platelets and slow down the clotting process.

Chemotherapy can cause irritation and dryness in the mouth and throat. Painful sores may form that can bleed and become infected. Precautions to avoid this side effect include getting dental care before chemotherapy begins, brushing the teeth and gums regularly with a soft brush, and avoiding mouth washes that contain salt or alcohol.

Chest drainage therapy

Definition

Chest drainage therapy involves the removal of air, blood, pus, or other secretions from the chest cavity.

Purpose

Chest drainage therapy is done to relieve pressure on the lungs, and remove fluid that could promote infection. Installing a chest drainage tube can be either an emergency or a planned procedure.

Removing air or fluids from the chest involves the insertion of a tube through the skin and the muscles between the ribs, and into the chest cavity. This cavity is also called the pleural space. Insertion of this tube is called thoracostomy, and chest drainage therapy is sometimes called thoracostomy tube drainage.

Conditions that may need to be treated by chest drainage therapy include **emphysema** (air in the tissues of the lungs), **tuberculosis**, and spontaneous pneumothorax (air in the chest cavity) that causes more than a 25% collapse of the lung. Other conditions include

KEY TERMS

Empyema—Pus in the pleural cavity.

Hemothorax—Blood in the pleural cavity.

Pleural cavity—The area of the chest that includes the lining of the chest cavity, the space the lungs are located in, and the membrane covering of the lungs.

Spontaneous pneumothorax—Air in the chest cavity that occurs because of disease or other naturally occurring cause. Air and blood together in this space is called a pneumohemothorax.

cancer that causes excessive secretions, **empyema** (pus in the thoracic cavity), or hemothorax (blood in the thoracic cavity). Almost all chest drainage therapy is done to drain blood from the chest cavity after lung or heart surgery. In cases where the lung is collapsed, removing fluids by chest drainage therapy allows the lung to reinflate.

Oftentimes an x ray is performed prior to treatment to determine whether the problem is either fluid or air in the pleural space. Sometimes a procedure called **thoracentesis** is performed in an effort to avoid inserting a chest drainage tube. In this procedure a needle with a catheter is inserted into the pleural space and fluid is removed. When fluid continues to accumulate, chest drainage therapy is usually the next step. This is especially true when there is a lung infection underlying the fluid build-up.

Precautions

Chest drainage therapy is not done if a collapsed lung is not life-threatening. It also should be avoided for patients who have blood clotting problems.

Description

Most patients are awake when the chest drainage tube is inserted. They are given a sedative and a local anesthetic. Chest drainage tubes are usually inserted between the ribs. The exact location depends on the type of material to be drained and its location in the lungs.

An incision is made in the skin and through the muscles between the ribs. A chest tube is inserted and secured in place. The doctor connects one end of the tube to the chest drainage system.

The chest drainage system must remain sealed to prevent air from entering the chest cavity through the tube. One commonly used system is a water-seal drainage system, comprised of three compartments that collect and drain the fluid or air without allowing air to backflow into the tube. An alternative to this system is to connect the tube to a negative suction pump.

Once the tube and drainage system are in place, a chest x ray is done to confirm that the tube is in the right location, and that it is working. In some cases it may be necessary to insert more than one tube to drain localized pockets of fluid that have accumulated.

Preparation

A chest x ray is usually done before the chest drainage tube is inserted. Sometimes fluid becomes trapped in isolated spaces in the lung, and it is necessary to do an **ultrasound** to determine where to locate the drainage tube. **Computed tomography scans** (CT) are useful in locating small pockets of fluids caused by cancer or tuberculosis.

Aftercare

Normally after the material has been removed from the chest cavity and the situation is resolved, the chest drainage tube is removed. In cases where the reason for the tube was air in the pleural cavity, the tube is clamped and left in place several hours before it is removed to make sure no more air is leaking into the space. If the patient is on mechanical ventilation, the tube is often left in place until a respirator is no longer necessary. Chest drainage therapy is usually done in conjunction with treating the underlying cause of the fluid build-up.

The fluid that has been drained is examined for bacterial growth, cancer cells, pus, and blood to determine the underlying cause of the condition and appropriate treatment.

Results

The gas, pus, or blood is drained from the chest cavity, and the lungs reinflate or begin to function more efficiently. The site at which the tube was inserted heals normally.

Risks

Problems can arise in the insertion of the tube if the membrane lining the chest cavity is thick or if it has many **adhesions**. The tube will not drain correctly if the

WWW.BOOKBAZ.IR

chest cavity contains **blood clots** or thick secretions that are often associated with infections. Excessive bleeding may occur during the insertion and positioning of the tube. Infection may result from the procedure. **Pain** is also a common complication.

Chest pain *see* **Angina**

Chest physical therapy

Definition

Chest **physical therapy** is the term for a group of treatments designed to improve respiratory efficiency, promote expansion of the lungs, strengthen respiratory muscles, and eliminate secretions from the respiratory system.

Purpose

The purpose of chest physical therapy, also called chest physiotherapy, is to help patients breathe more freely and to get more oxygen into the body. Chest physical therapy includes postural drainage, chest percussion, chest vibration, turning, deep breathing exercises, and coughing. It is usually done in conjunction with other treatments to rid the airways of secretions. These other treatments include suctioning, nebulizer treatments, and the administration of expectorant drugs.

Chest physical therapy can be used with newborns, infants, children, and adults. People who benefit from chest physical therapy exhibit a wide range of problems that make it difficult to clear secretions from their lungs. Some people who may receive chest physical therapy include people with **cystic fibrosis** or neuromuscular diseases like Guillain-Barré syndrome, progressive muscle weakness (**myasthenia gravis**), or **tetanus**. People with lung diseases such as **bronchitis**, **pneumonia**, or **chronic obstructive pulmonary disease** (COPD) also benefit from chest physical therapy. People who are likely to aspirate their mucous secretions because of diseases such as **cerebral palsy** or **muscular dystrophy** also receive chest physical therapy, as do some people who are bedridden, confined to a wheelchair, or who cannot breathe deeply because of postoperative **pain**.

Precautions

Chest physical therapy should not be performed on people with

- bleeding from the lungs
- neck or head injuries
- fractured ribs
- collapsed lungs
- damaged chest walls
- tuberculosis
- acute asthma
- recent heart attack
- pulmonary embolism
- lung abscess
- active hemorrhage
- some spine injuries
- recent surgery, open wounds, or burns

Description

Chest physical therapy can be performed in a variety of settings including critical care units, hospitals, nursing homes, outpatient clinics, and at the patient's home. Depending on the circumstances, chest physical therapy may be performed by anyone from a respiratory care therapist to a trained member of the patient's family. Different patient conditions warrant different levels of training.

Chest physical therapy consists of a variety of procedures that are applied depending on the patient's health and condition. Hospitalized patients are reevaluated frequently to establish which procedures are most effective and best tolerated. Patients receiving long term chest physical therapy are reevaluated about every three months.

Turning

Turning from side to side permits lung expansion. Patients may turn themselves or be turned by a caregiver. The head of the bed is also elevated to promote drainage if the patient can tolerate this position. Critically ill patients and those dependent on mechanical respiration are turned once every one to two hours around the clock.

KEY TERMS

Coughing—Coughing helps break up secretions in the lungs so that the mucus can be suctioned out or expectorated. Patients sit upright and inhale deeply through the nose. They then exhale in short puffs or coughs. Coughing is repeated several times per day.

Deep breathing—Deep breathing helps expand the lungs and forces better distribution of the air into all sections of the lung. The patient either sits in a chair or sits upright in bed and inhales, pushing the abdomen out to force maximum amounts of air into the lung. The abdomen is then contracted, and the patient exhales. Deep breathing exercises are done several times each day for short periods.

Percussion—This consists of rhythmically striking the chest wall with cupped hands. It is also called cupping, clapping, or tapotement. The purpose of percussion is to break up thick secretions in the lungs so that they can be more easily removed. Percussion is performed on each lung segment for one to two minutes at a time.

Postural drainage—This technique uses the force of gravity to assist in effectively draining secretions from the lungs and into the central airway where they can either be coughed up or suctioned out. The patient is placed in a head or chest down position and is kept in this position for up to 15 minutes. Critical care patients and those depending on mechanical ventilation receive postural drainage therapy four to six times daily. Percussion and vibration may be performed in conjunction with postural drainage.

Turning—Turning from side to side permits lung expansion. Patients may turn themselves or be turned by a caregiver. The head of the bed is also elevated to promote drainage if the patient can tolerate this position. Critically ill patients and those dependent on mechanical respiration are turned once every one to two hours around the clock.

Vibration—The purpose of vibration is to help break up lung secretions. Vibration can be either mechanical or manual. It is performed as the patient breathes deeply. When done manually, the person performing the vibration places his or her hands against the patient's chest and creates vibrations by quickly contracting and relaxing arm and shoulder muscles while the patient exhales. The procedure is repeated several times each day for about five exhalations.

Coughing

Coughing helps break up secretions in the lungs so that the mucus can be suctioned out or expectorated. Patients sit upright and inhale deeply through the nose. They then exhale in short puffs or coughs. Coughing is repeated several times a day.

Deep breathing

Deep breathing helps expand the lungs and forces better distribution of the air into all sections of the lung. The patient either sits in a chair or sits upright in bed and inhales, pushing the abdomen out to force maximum amounts of air into the lung. The abdomen is then contracted, and the patient exhales. Deep breathing exercises are done several times each day for short periods.

Postural drainage

Postural drainage uses the force of gravity to assist in effectively draining secretions from the lungs and into the central airway where they can either be coughed up or suctioned out. The patient is placed in a head or chest down position and is kept in this position for up to 15 minutes. Critical care patients and those depending on mechanical ventilation receive postural drainage therapy four to six times daily. Percussion and vibration may be performed in conjunction with postural drainage.

Percussion

Percussion is rhythmically striking the chest wall with cupped hands. It is also called cupping, clapping, or tapotement. The purpose of percussion is to break up thick secretions in the lungs so that they can be more easily removed. Percussion is performed on each lung segment for one to two minutes at a time.

Vibration

As with percussion, the purpose of vibration is to help break up lung secretions. Vibration can be either mechanical or manual. It is performed as the patient breathes deeply. When done manually, the person performing the vibration places his or her hands against the patient's chest and creates vibrations by quickly contracting and relaxing arm and shoulder muscles

WWW.BOOKBAZ.IR

while the patient exhales. The procedure is repeated several times each day for about five exhalations.

Preparation

The only preparation needed for chest physical therapy is an evaluation of the patient's condition and determination of which chest physical therapy techniques would be most beneficial.

Aftercare

Patients practice **oral hygiene** procedures to lessen the bad taste or odor of the secretions they spit out.

Results

The patient is considered to be responding positively to chest physical therapy if some, but not necessarily all, of these changes occur:

- increased volume of sputum secretions
- changes in breath sounds
- improved vital signs
- improved chest x ray
- increased oxygen in the blood as measured by arterial blood gas values
- patient reports of eased breathing

Risks

Risks and complications associated with chest physical therapy depend on the health of the patient. Although chest physical therapy usually poses few problems, in some patients it may cause

- oxygen deficiency if the head is kept lowered for drainage
- increased intracranial pressure
- temporary low blood pressure
- bleeding in the lungs
- pain or injury to the ribs, muscles, or spine
- vomiting
- inhaling secretions into the lungs
- heart irregularities

Chest radiography *see* **Chest x ray**

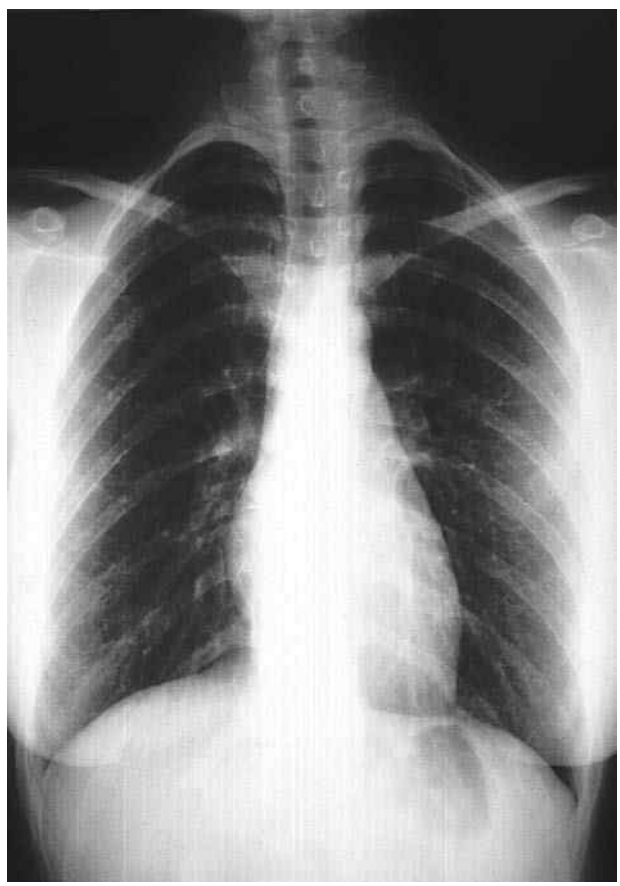
Chest x ray

Definition

A chest x ray is a procedure used to evaluate organs and structures within the chest for symptoms of disease. Chest x rays include views of the lungs, heart, small portions of the gastrointestinal tract, thyroid gland, and the bones of the chest area. X rays are a form of radiation that can penetrate the body and produce an image on an x-ray film. Another name for the film produced by x rays is radiograph.

Purpose

Chest x rays are ordered for a wide variety of diagnostic purposes. In fact, this is probably the most frequently performed type of x ray. In some cases, chest x rays are ordered for a single check of an organ's condition, and at other times, serial x rays are ordered to compare to previous studies. Chest x rays are often ordered if a persistent **cough**, chest injury, chest **pain**, coughing up blood, or difficulty breathing are present.



Normal adult chest x ray. *(Custom Medical Stock Photo, Inc.)*

Pulmonary disorders

Chest films are frequently ordered to diagnose or rule out **pneumonia**. One type, **tuberculosis**, can be observed on chest x rays, as can cardiac disease and damage to the ribs or lungs. Other pulmonary disorders such as pneumothorax (presence of air or gas in the chest cavity outside the lungs) or **emphysema** may be detected or evaluated through the use of chest x ray.

Cancer

A chest x ray may be ordered by a physician to check for possible tumors of the lungs, lymphoid tissue, or bones of the thorax. These may be primary tumors or the areas in which cancer originates in the body. X rays may also detect the secondary spread of cancer from another organ to the chest.

Cardiac disorders

While less sensitive than **echocardiography**, chest x ray can be used to check for disorders such as **congestive heart failure** or **pulmonary edema**.

Other

Chest x rays are used to see foreign bodies that may have been swallowed or inhaled and to evaluate response to treatment for various diseases. Often the chest x ray is also used to verify correct placement of chest tubes or catheters. Chest x rays can be used to check for fluid surrounding the lungs (**pleural effusion**).

Description

Routine chest x rays consist of two views, the frontal view (referred to as posterior-anterior or PA) and the lateral (side) view. It is preferred that the patient stand for this exam, particularly when studying collection of fluid in the lungs.

During the actual time of exposure, the technologist will ask the patient to hold his or her breath. It is very important in taking a chest x ray to ensure there is no motion that could detract from the quality and sharpness of the film image. The procedure will only take a few minutes and the time patients must hold their breath is a matter of a few seconds.

The chest x ray may be performed in a physician's office or in an outpatient **radiology** facility or hospital radiology department. In some cases, particularly for patients who cannot get out of bed, a portable chest x ray may be taken. Portable films are sometimes of poorer quality than those taken with permanent equipment but are the best choice for some patients or situations when the patient cannot be moved or properly positioned for the chest x ray. Patients confined to bed may be placed in as upright a position as possible to get a clear picture, particularly of chest fluid.

KEY TERMS

Bronchi—Plural of bronchus, the air passages in the lungs through which inhaled air passes on its way through the lungs.

Diaphragm—The large muscle that is located between the abdomen and the chest area. The diaphragm aids in breathing.

Gastrointestinal—The digestive organs and structures, including the stomach and intestines.

Interstitial lung disease—A category of lung disease that can lead to breathing or heart failure; injury or foreign substances in the lungs (such as asbestos fibers), infections, cancers, or inherited disorders may cause one of the 180 conditions classified as interstitial lung disease.

Lymphoid—Tissues relating to the lymphatic system. A thin, yellowish fluid called lymph fluid, travels throughout the body. The lymphatic system helps control fluids in the body.

Portable chest x ray—An x-ray procedure taken by equipment that can be brought to the patient. The resulting radiographs may not be as high in quality as stationary x-ray radiographs, but they allow a technologist to come to the patient.

Pulmonary—Refers to the lungs and the breathing system and function.

Serial x rays—A number of x rays performed at set times in the disease progression or treatment intervals. The radiographs will be compared to one another to track changes.

Sternum—Also referred to as the breast bone; the long flat bone in the middle of the chest.

Thorax—The chest area, which runs between the abdomen and neck and is encased in the ribs.

X ray—A form of electromagnetic radiation with shorter wavelengths than normal light. X rays can penetrate most structures.

Preparation

There is no advance preparation necessary for chest x rays. The patient wears a hospital gown on the upper body, and all jewelry is removed.

WWW.BOOKBAZ.IR

Aftercare

No aftercare is required by patients who have chest x rays.

Results

A radiologist, or physician specially trained in the technique and interpretation of x rays, evaluates the results. A normal chest x ray shows normal structures for the age and medical history of the patient. Findings, whether normal or abnormal, are provided to the referring physician in the form of a written report.

Risks

The only risk associated with chest x ray is minimal exposure to radiation, particularly for pregnant women and children. Those patients should use protective lead aprons during the procedure. Technologists are cautioned to check carefully possible dislodging of any tubes or monitors in the chest area from the patient's placement during the exam.

Abnormal findings on chest x rays are used in conjunction with a physician's physical exam findings, patient medical history, and other diagnostic tests—including laboratory tests—to reach a final diagnosis. For many diseases, chest x rays are more effective when compared to previous chest x-ray studies. The patient is asked to help the radiology facility in locating previous chest radiographs from other facilities.

Pulmonary disorders

Pneumonia shows up on radiographs as patches and irregular areas of density (from fluid in the lungs). If the bronchi (air passages in the lungs that are usually not visible) can be seen, a diagnosis of bronchial pneumonia may be made. Shifts or shadows in the hila (lung roots) may indicate enlarged lymph nodes of a malignancy. Widening of the spaces between ribs and increased lucency of the lung fields suggests emphysema. Other pulmonary diseases may also be detected or suspected through chest x ray.

Cancer

In nearly all patients with lung cancer, some sort of abnormality can be seen on a chest radiograph. Hilar masses (enlargements at the part of the lungs where vessels and nerves enter) are one of the more common symptoms, as are abnormal masses and fluid buildup on the outside surface of the lungs or surrounding areas. Interstitial lung disease—which includes a large category of disorders, many of which are related to exposure of substances (such as asbestos fibers)—may be detected on a chest x ray as increased prominence of the interstitial pattern, often in the lower portions of the lungs.

Other

Congestive **heart failure** and other cardiac diseases may be indicated on the view of a heart and lung in a chest radiograph. **Fractures** of the sternum and ribs are sometimes detected as breaks on the chest x ray, though often dedicated bone films are needed. In some instances, the radiologist's view of the diaphragm may indicate an abdominal problem. Foreign bodies that may have been swallowed or inhaled can usually be located by the radiologist, as they will look different from any other tissue or structure in the chest. Serial chest x rays may be ordered to track changes over a period of time, usually to evaluate response to therapy of a malignancy.

REVISED BY KARL FINLEY

Chickenpox

Definition

Chickenpox is a common and highly contagious childhood disease that also occasionally affects adults. It is caused by the varicella–zoster virus. Chickenpox produces an itchy, blistery rash that typically lasts about a week and is sometimes accompanied by **fever** or other symptoms.

Demographics

Chickenpox is a common **infectious disease** with an estimated 60 million cases occurring annually worldwide. In temperate regions, the disease usually affects children under age 10; in tropical regions, adult cases are more common. The rate of infection is independent of race or gender, but is much lower in countries where **vaccination** against the disease is practiced. For example, before a vaccine against chickenpox was introduced in the United States in 1995, about 99% of the population got chickenpox by age 30. A decade after the vaccine was introduced, only about 10% of Americans who had not already had chickenpox got the disease.

A five-year-old girl with chickenpox. The first symptom of the disease is the rash that is evident on the girl's back and neck. The rash and the mild fever that accompanies it should disappear in a week or two. *(Jim Selby/Photo Researchers, Inc.)*

Description

Chickenpox is very contagious. The virus is transmitted through either direct contact or coughing and sneezing. A person with chickenpox is contagious from one to two days before the outbreak of the chickenpox rash to about six days after the rash erupts. After being exposed, a person will show symptoms of chickenpox within 10–21 days. Individuals normally get chickenpox only once in a lifetime.

Most cases of chickenpox contracted by healthy children are mild, with the child experiencing seven to 10 days of discomfort. However, in children who are immunocompromised, such as those with leukemia, **AIDS**, or who are undergoing **immunosuppression** therapy in connection with an organ transplant, chickenpox can have serious complications including death. For example, the number of children with leukemia who die of complications from chickenpox is estimated at 7% to 28%. This compares to a death rate of about seven in every 100,000 healthy children. Abnormalities may occur in the fetuses of women who develop chickenpox during the first 22 weeks of **pregnancy**.

Risk factors

The greatest risk factor for acquiring chickenpox is the failure to vaccinate; almost every unvaccinated person exposed to the virus develops chickenpox. It may not be safe to vaccinate some children with compromised immune systems, leaving them highly vulnerable to both the disease and severe complications including death. Pregnant women who develop chickenpox during the first half of their pregnancy put the fetus at risk for **birth defects**.

Causes and symptoms

Chickenpox is caused by the varicella–zoster virus, a member of the herpes virus family. It easily spreads through the air or by direct contact with an infected person.

A case of chickenpox usually starts without warning or with only a mild fever and a slight feeling of illness. Within a few hours or days, small red spots

WWW.BOOKBAZ.IR

KEY TERMS

Acetaminophen—A drug for relieving pain and fever. Tylenol is the most common example.

Acyclovir—An antiviral drug used for combating chickenpox and other herpes viruses.

Dehydration—Excessive water loss by the body.

Encephalitis—A rare viral infection that causes inflammation in the membranes lining the brain.

Hepatitis—A disease that causes inflammation of the liver and serious liver damage.

Immune system—A mechanism that protects the body from foreign substances, foreign cells, and pathogens (viruses, bacteria). The thymus, spleen, lymph nodes, white blood cells, including the B cells and T cells, and antibodies are involved in the immune response, which aims to destroy these foreign bodies.

Immunocompromised—Having a damaged immune system.

Passive immunity—Immunity produced by providing a person with antibodies from another source than self. Infants are born with passive immunity acquired from their mothers.

Pneumonia—A disease that causes inflammation of the lungs. It can be caused by a bacterium or a virus.

Pus—A thick yellowish or greenish fluid containing inflammatory cells. Usually caused by bacterial infection.

Reye's syndrome—A rare but often fatal disease that involves the brain, liver, and kidneys. It may be brought on by giving salicylates to children (but not adults) who have a viral infection.

Salicylates—A group of drugs that includes aspirin and related compounds. Salicylates are used to relieve pain, reduce inflammation, and lower fever.

Shingles—A disease also called herpes zoster that causes a rash and a very painful nerve inflammation. An attack of chickenpox eventually gives rise to shingles in about 20% of the population.

Vaccination—Injection of a killed or weakened microbe in order to stimulate the immune system against the microbe, thereby preventing disease. Vaccinations, or immunizations, work by stimulating the immune system, the natural disease–fighting system of the body. The healthy immune system is able to recognize invading bacteria and viruses and produce substances (antibodies) to destroy or disable them. Vaccinations prepare the immune system to ward off a disease. To immunize against viral diseases, the virus used in the vaccine has been weakened or killed.

Varicella–zoster immune globulin (VZIG)—A substance that can reduce the severity of chickenpox symptoms.

Virus—A tiny particle that can cause infections by duplicating itself inside a cell using the cell's own reproductive mechanisms. Antibiotics are generally ineffective against viruses, though antiviral drugs exist for some viruses, including chickenpox.

begin to appear on the scalp, neck, or upper half of the trunk. After a further 12–24 hours, the spots typically become itchy, fluid–filled bumps called vesicles, which continue to appear for the next two to five days. In any area of skin, lesions in a variety of stages can be seen. These blisters can spread to cover much of the skin, and in some cases may be found inside the mouth, nose, ears, vagina, or rectum. Some people develop only a few blisters, but in most cases the number reaches 250–500.

The blisters soon begin to form scabs and fall off. Scarring usually does not occur unless the blisters have been scratched and become infected. Occasionally a minor and temporary darkening of the skin (called **hyperpigmentation**) develops around some of the blisters. The degree of itchiness can range from barely noticeable to extreme. Some people who contract chickenpox also have headaches, abdominal **pain**, or a fever. Full recovery usually takes five to 10 days after the first symptoms appear. The most severe cases of the disease tend to be found among adolescents and adults.

Although for most people chickenpox is no more than a matter of a few days of discomfort, some groups are at risk for developing complications, the most common of which are bacterial infections of the blisters, **pneumonia**, **dehydration**, encephalitis, and hepatitis:

- Infants. Complications occur much more often among children less than one year old than among older children. The threat is greatest to newborns, who are more at risk of death from chickenpox than any other group. Under certain circumstances, children born to mothers who contract chickenpox just

before delivery develop the disease and face an increased possibility of dangerous complications, including brain damage and death. If the infection occurs during the first half of pregnancy, there is a small risk of the baby being born with congenital abnormalities.

- Immunocompromised children. Children whose immune systems have been weakened by a genetic disorder, disease, or medical treatment usually experience the most severe symptoms of any group. They have the second–highest rate of death from chickenpox.
- Adults and children age 15 and older. Among this group, typical symptoms of chickenpox tend to be more severe, and the risk of complications is much higher than among young children. Adults are ten times more likely than children to require hospitalization from chickenpox.

Diagnosis

For otherwise healthy children, especially those with recent exposure to the disease, diagnosis usually can be made at home, by a school nurse, or by a doctor if the child's parent or caregiver is unsure that the disease is chickenpox. A doctor should be called immediately if:

- The child has a chronic disease or is undergoing a treatment that weakens the immune system.
- The child's fever goes above 102°F (38.9°C) or takes more than four days to disappear.
- The child's blisters appear infected. Signs of infection include pus drainage or excessive redness, warmth, tenderness, or swelling.
- The child seems nervous, confused, unresponsive, or unusually sleepy; complains of a stiff neck or severe headache; shows signs of poor balance or has trouble walking; finds bright lights hard to look at; is having breathing problems or is coughing a lot; is complaining of chest pain; is vomiting repeatedly; or is having convulsions. These may be signs of Reye's syndrome or encephalitis, two rare but potentially very dangerous conditions.

Treatment

Home remedies

Treatment usually takes place at home and focuses on reducing discomfort and fever. The individual should drink plenty of fluids and eat simple, nutritious foods. Soups, herbal teas, and fruit juices are good choices. If mouth blisters make eating or drinking an unpleasant experience, cold drinks and soft, bland foods can ease the discomfort.

Applying wet compresses or bathing in cool or lukewarm water once a day can help the itch. Adding four to eight ounces of baking soda or one to two cups of oatmeal to the bath may help ease **itching**. Oatmeal bath packets are sold by pharmacies. Only mild soap should be used in the bath. Patting, not rubbing, is recommended for drying off to prevent irritating the blisters. Calamine lotion also helps to reduce itchiness. Because scratching can cause blisters to become infected and lead to scarring, a child's nails should be cut short. Older children need to be warned not to scratch. For babies, light mittens or socks on the hands can help guard against scratching.

Drugs

Fever and discomfort can be reduced by **acetaminophen** (Tylenol, Tempera). **Aspirin** and any medications that contain aspirin or other salicylates must not be used for children with chickenpox because they appear to increase the chances of developing Reye's syndrome. The best idea is to consult a doctor or pharmacist if unsure about which medications are safe.

Because chickenpox is a viral disease, **antibiotics** are ineffective against it, although antibiotics may be prescribed if blisters become infected.

Children who are immunocompromised or healthy children who develop serious complications are often treated with the antiviral drug acyclovir (Zovirax), which is given intravenously. This drug may also be used under certain circumstances in adolescents and adults with chickenpox.

A substance called varicella–zoster immune globulin (VZIG), which reduces the severity of chickenpox symptoms, may be used to treat immunocompromised children and others at high risk of developing complications. VZIG is produced from a **gamma globulin** from blood of recently infected individuals. It provides some degree of passive immunity when administered by injection within 96 hours of known or suspected exposure to the disease. It is not useful if given more than 96 hours after exposure.

Alternatives

Alternative practitioners recommend a variety of treatments with the aim of reducing discomfort, strengthening the immune system, and speeding healing. An alternative practitioner should be consulted about the best choice for each individual.

WWW.BOOKBAZ.IR

SUPPLEMENTS. **Vitamin A** may help to heal damaged skin. Vitamin C and bioflavonoids may help to reduce fever and stimulate the immune system. Zinc stimulates the immune system and is thought to promote healing; however zinc can cause **nausea and vomiting**. **Calcium** and magnesium may help to relieve restlessness and sleeping difficulties, but magnesium has a laxative effect at high doses.

HERBALS AND CHINESE MEDICINE. The following herbals may used internally (ingested) to treat chickenpox:

- Echinacea and goldenseal (*Hydrastis canadensis*) support the immune system and soothe skin and mucous membranes. Echinacea is also thought to have antiviral properties.
- Chamomile tea is a sleep aid.
- Chinese cucumber (*Trichosanthes kirilowii*) root tea is used to relieve symptoms of chickenpox.
- Elder flower, peppermint, and yarrow may reduce fever.
- Garlic has antiviral activity.
- Mullein (*Verbascum thapsus*).
- Yin Qiao Jie Du Wan (Honeysuckle and Forsythia Pill).
- Ban Lan Gen Chong Ji (Isatis Infusion).

The following herbals are used externally (applied to skin) to treat chickenpox:

- Aloe leaf, calendula, and plantain relieve the itching of the chickenpox rash.
- Turmeric powder mixed with lime juice treats chickenpox rash.
- Garlic helps clear skin infection.

OTHER ALTERNATIVE REMEDIES. Homeopathic remedies are selected on a case–by–case basis. Some common remedy choices are apis, aconitum, belladonna, calendula, antimonium tartaricum, pulsatilla,*Rhus toxicodendron*, and sulphur.

The **acupressure** points Four Gates, Large Intestine 11, Spleen 10, and Stomach 36 help alleviate symptoms associated with chickenpox.

Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

Prognosis

Most cases of chickenpox run their course within a week. Although complications from chickenpox generally are rare, the most common one is bacterial infection of the skin, initiated at the site of a chickenpox blister that has broken or was scratched open. Other complications include viral or bacterial pneumonia and rarely encephalitis (swelling of the brain). Anyone with a weakened immune system, lung diseases, **eczema** or other skin conditions, infants under one year of age, premature infants whose mothers have not had chickenpox, and newborns whose mothers had chickenpox around the time of delivery are at highest risk for developing complications are.

After symptoms subside, the varicella–zoster virus lies dormant in nerve cells where it may be reactivated years later by disease or age–related weakening of the immune system. The result is **shingles** (herpes zoster), a very painful rash and nerve inflammation, that develops in between 10% and 20% of all people who have ever had chickenpox. Shingles is particularly common in people over age 50. Shingles cause numbness, itching, or severe pain in skin areas where the affected nerve root is located. Within about three days cause clusters of blisters to form along the affected nerve. The blisters last two to three weeks. A vaccine against shingles is recommended for individuals age 60 and older.

Prevention

Vaccination against the varicella–zoster virus is the best way of preventing chickenpox. Vaccination has been proven to be about 85% effective for preventing all cases of chickenpox and about 95% effective in preventing severe cases. Side effects of the vaccine normally are limited to occasional soreness or redness at the injection site. The United States Centers for Disease Control and Prevention (CDC) guidelines state that the vaccine should be given to all children (with the exception of certain high–risk groups) at 12–18 months of age, preferably when they receive their measles–mumps–rubella (MMR) vaccine. For older children, up to age 12, the CDC recommends vaccination when a reliable determination that the child in question has already had chickenpox cannot be made. Vaccination also is recommended for any older child or adult considered susceptible to the disease, particularly those, such as health care workers and women of childbearing age.

A single dose of the vaccine was once thought sufficient for children up to age 12; older children and adults received a second dose four to eight weeks later. However, an outbreak at a daycare center in 2000 brought concern in the medical community about the permanence of immunity and the necessity of a second vaccination for younger children, since many of the affected children had already received a

single dose of the vaccine. Since 2006, a second dose of the vaccine has become standard.

The chickenpox vaccine is not recommended for pregnant women, and women should delay pregnancy for three months following a complete vaccination. The vaccine is useful when given early after exposure to chickenpox and, if given in the midst of the incubation period, it may be preventative.

While there was initial concern regarding the vaccine's safety and effectiveness when first released, the vaccination has gained acceptance, and many states require it for admittance into daycare or public school. In 2004, 87.5% of toddlers ages 19–35 months in the United States were immunized; up nearly 20% from 2000.

The vaccine was approved for use in Australia in 2000 and is recommended for children starting at age 18 months. Between 2000 and 2006, 1.3 million doses of the vaccine have been given in Australia, with 342 reports of adverse effects and 115 reports of the vaccine' giving only partial protection, according to the Australian Adverse Drug Reaction Committee.

REVISED BY TISH DAVIDSON, A.M.

Chikungunya

Definition

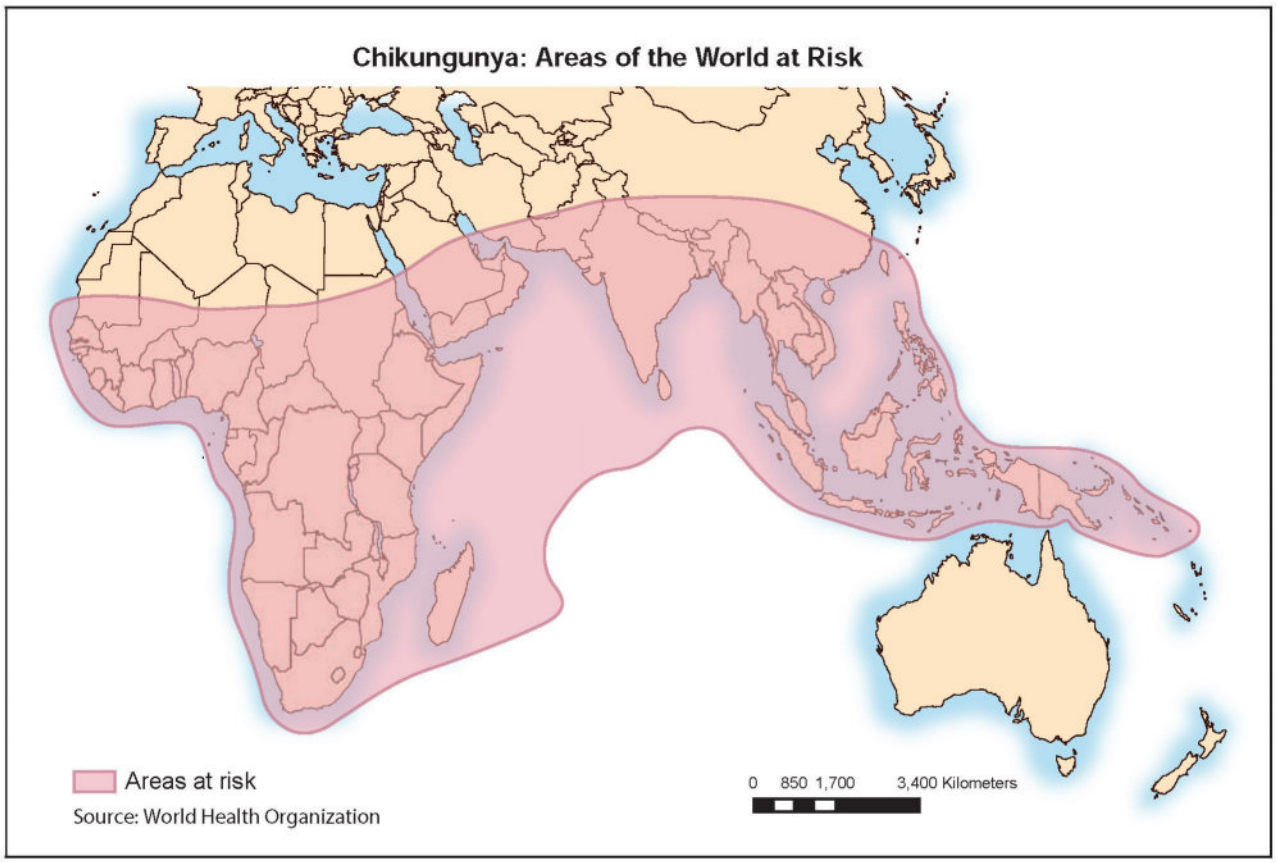
Chikungunya is an emerging global viral disease transmitted by mosquitoes. Although seldom fatal, it causes a very painful illness characterized by arthritis-like joint **pain** and **fever**.

Description

Chikungunya is caused by an arbovirus. Arboviruses have single-stranded RNA as their genetic material and are transmitted by arthropods, most often mosquitoes. There about 500 known arboviruses, including the viruses that cause **yellow fever**, encephalitis, and dengue. The chikungunya virus is a member of the *Alphavirus* genus in the family Togaviridae. *Chikungunya* means "to become contorted" in the Kimakonde language of the Makonde people who live on the eastern border of Tanzania and Mozambique, where the disease was first identified. The name refers to the appearance of victims suffering from joint pain (arthralgia) caused by the disease.

The chikungunya virus was first transmitted to people by *Aedes aegypti* mosquitoes that also transmit the viruses that cause dengue and yellow fever. A single amino acid change enabled it to be transmitted by the Asian tiger mosquito *Aedes albopictus*. This broadening of vectors occurred in 2006 on the island of La Réunion to the east of Madagascar. Such mutations occur often in RNA viruses because there are high error rates during replication (copying) of their genetic material to ensure their adaptability to changing conditions. Indeed, this doubling of vector species has facilitated the global spread of chikungunya because, whereas *A. aegypti* is limited to the tropics and subtropics, *A. albopictus* has a much wider distribution, ranging into temperate and cold-temperate regions. *A. albopictus* increased its range in the second half of the twentieth century from Asia to parts of

WWW.BOOKBAZ.IR



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Africa, Europe, and the Western Hemisphere, at least in part due to rising global temperatures. *A. albopictus* also has a wider range of breeding sites than *Ae. aegypti*. *A. aegypti* is closely associated with human dwellings, breeding indoors in flower vases, water-storage containers, and concrete bathroom water tanks, as well as outdoor artificial habitats such as vehicle tires and planters. *A. albopictus* uses all of those breeding sites but also breeds in natural habitats, such as cocoa pods, bamboo stumps, coconut husks, tree holes, and rock pools. Thus, *A. albopictus* thrives in both rural and suburban areas, as well as urban shady parks.

Both *A. aegypti* and *A. albopictus* transmit the dengue virus as well as the chikungunya virus. It is possible that several other mosquito vectors also transmit chikungunya in Africa, including species in the *Aedes furcifer-taylori* group and *Aedes luteocephalus*. During epidemics, humans are the primary host for the chikungunya virus. However, there is evidence that some animals, such as rodents and other small mammals and birds, may serve as viral reservoirs.

Risk factors

The major risk factor for chikungunya is residing near *Aedes* mosquito breeding sites. Newborns, adults aged 65 and older, and people with chronic medical conditions such as high blood pressure, diabetes, and **heart disease** are most at risk for severe infection.

Demographics

Since it was first identified during a 1952 outbreak in southern Tanzania, chikungunya has infected tens of millions of people throughout central and southern Africa, Southeast Asia, the Indian subcontinent, and islands in the Indian and Pacific Oceans, reaching epidemic proportions since 2004. The disease reached Europe in 2007, with a localized outbreak of 197 reported cases in northeastern Italy and subsequent infections reported from France.

In December of 2013, locally transmitted chikungunya infections were reported from the Caribbean island of St. Martin. Once introduced into populations that had never been exposed to the virus and so had virtually no immunity, chikungunya spread quickly.

Within six months, approximately 440,000 cases had been reported from throughout the Caribbean and surrounding Central and South American countries. In June of 2014, chikungunya had reached epidemic proportions in Puerto Rico. There was a 24% increase in Caribbean cases in the week ending July 18 alone, including 250,000 cases in the Dominican Republic and 50,000–63,000 each in Haiti, Guadeloupe, and Martinique. The disease was continuing to spread to the mainland, with reports from El Salvador, Costa Rica, Venezuela, Guyana, French Guiana, and Suriname. Although rarely lethal, 26 people in this first Western Hemisphere chikungunya epidemic had died as of July, 2014. Although a number of infections had been reported in Americans returning from international travel, the first two known cases acquired in the United States were reported from Florida in July. The mosquitoes that carry the chikungunya virus are predominately found in the southern and parts of the western United States.

Although chikungunya has remained at relatively low levels in Africa for a number years, there was a large outbreak in the Democratic Republic of Congo in 1999–2000 and an outbreak in Gabon in 2007. There was a major outbreak in 2005–2006 in islands in the Indian Ocean, with many cases imported to Europe. There was also a large outbreak in India in 2006–2007. There have been more than 1.9 million cases reported from India, Indonesia, Thailand, Myanmar, and Maldives since 2005.

Causes and symptoms

Causes

Aedes mosquitoes pick up the chikungunya virus when they feed on the blood of an infected person. They then transmit the virus to people they subsequently bite. Both *A. aegypti* and *A. albopictus* bite outdoors during the daylight hours, with possible peaks in the early morning and late afternoon. *A. aegypti* also feeds indoors. The risk of transmission is greatest during the first week of illness, when the concentration of virus in the blood is highest.

Rarely, the chikungunya virus can be transmitted from mother to child during **pregnancy**, primarily during the second trimester, and at the time of birth (perinatally) if the mother is viremic—has the virus in her blood. The virus has not been found in breast milk. The chikungunya virus can theoretically be transmitted through **transfusion** with infected blood, although no such cases have been reported. There have been documented cases of transmission to laboratory workers handling infected blood, and there is one reported case of a healthcare worker becoming infected while drawing blood from an infected patient.

Symptoms

Most first infections with chikungunya result in at least some symptoms, although the symptoms are often mild and may go undiagnosed or be mistaken for dengue in regions where both viruses are endemic. Symptoms usually appear four-to-eight days after a bite by an infected mosquito, with a range of two to 12 days. The first symptom is abrupt onset of high fever, often accompanied by joint pain and swelling, especially in the hands and feet. Other common symptoms are also similar to dengue and include:

- muscle pain
- headache
- nausea
- rash
- fatigue

The joint pain is severe and extremely debilitating. Although it usually lasts only a few days, it sometimes continues for weeks. Most patients recover fully within about ten days, but about 10–12% of people develop chronic arthritis that may last months or even years.

The infection appears to confer permanent immunity to future chikungunya infection; however, most Europeans and North and South Americans have never been exposed to the virus and thus have no immunity.

Diagnosis

Examination

Chikungunya is diagnosed by the acute onset of high fever and severe arthralgia in patients who reside in or have recently traveled to regions where the disease is endemic. Chikungunya and dengue are transmitted by the same mosquitoes and produce similar symptoms. The viruses may be endemic to the same areas, and co-infections are possible. High fever, severe arthralgia, arthritis, and rash are more common with chikungunya, whereas hemorrhage, **shock**, and death are more likely from dengue. It is important to distinguish between the diseases because proper management of dengue can significantly improve its prognosis.

Tests

The chikungunya virus, viral RNA, or antibodies against the virus can be detected in blood plasma or

WWW.BOOKBAZ.IR

KEY TERMS

***Aedes*—**A large genus of mosquitoes; *A. aegypti* and *A. aldopictus* transmit chikungunya and related viruses.

Antibodies—Specific proteins produced by the immune system in response to specific foreign proteins or particles such as viruses.

Arbovirus—Any of various RNA viruses that are primarily transmitted by mosquitoes and cause diseases such as chikungunya, yellow fever, encephalitis, and dengue.

Arthralgia—Joint pain.

Dengue—A viral disease transmitted by *Aedes* mosquitoes with symptoms similar to chikungunya.

Endemic—Restricted or peculiar to a specific locale or region; especially a disease that is prevalent only in particular populations.

Enzyme-linked immunosorbent assay (ELISA)—An immunological test for detecting specific substances, including viruses and antibodies.

Epidemic—Affecting many individuals in a community or population and spreading rapidly.

Immunoglobulin M (IgM)—A type of antibody that is produced early in an infection.

Outbreak—A sudden increase in the incidence of a disease.

Permethrin—A common neurotoxic insecticide and insect repellent that it used to treat clothing and equipment.

Reservoir—An animal species that harbors a virus, usually without symptoms of infection, and can transmit it to humans, either directly or via a vector.

Vector—An organism that can transmit infection from one organism or source to another; often a mosquito, tick, or rodent.

Viremic—The presence of viruses in the blood.

serum. The virus can be detected by culturing during the first three days of illness. Viral RNA may be detected in serum by reverse-transcription polymerase chain reaction (RT-PCR) during the first eight days of illness. Antibodies generally develop near the end of the first week of illness and can be detected by enzyme-linked immunosorbent assays (ELISA). Immunoglobulin M (IgM) antibody levels are highest three-to-five weeks after onset of the illness and persist for about two months. Therefore, if viral culturing or RNA tests are negative, antibody testing as the illness subsides may provide a definitive diagnosis. Because chikungunya requires handling under special laboratory conditions (biosafety level 3), in the United States as of 2014, tests were only performed at the Centers for Disease Control and Prevention (CDC), a few state health laboratories, and one commercial lab.

Blood tests may help distinguish between chikungunya and dengue. Dengue tends to cause decreases in immune system cells called neutrophils and in blood platelets that can lead to dengue hemorrhagic fever, whereas chikungunya tends to cause an overall drop in immune system lymphocytes.

Treatment

There is no treatment or cure for chikungunya. The illness almost always subsides on its own.

Physiotherapy may help relieve the joint pain.

Drugs

Non-steroidal anti-inflammatory drugs (NSAIDs)—such as ibuprofen, naproxen, **acetaminophen**, or paracetamol—or **corticosteroids** can help reduce fever and pain.

Alternatives

Resting and drinking fluids to prevent **dehydration** are important and may lessen symptoms.

Prognosis

Chikungunya generally subsides within a week, although in some cases joint pain may persist for weeks, months, or even years. The disease is rarely fatal, and serious complications are uncommon; however, there have been reports of occasional eye, neurological, and heart complications. In older people, chikungunya may contribute to the cause of death, but it is very rare for the disease to be the sole cause of death.

Prevention

The best protection against chikungunya is to avoid mosquito bites and prevent mosquito breeding. People at risk for severe disease should avoid traveling to regions where chikungunya outbreaks are ongoing. It is very important to avoid mosquito bites during the first week of illness, since this can further transmit the virus. An appropriate, long-lasting mosquito repellent

should be used and reapplied as directed. Repellent should not be sprayed on skin underneath clothing. Children's hands, eyes, and mouth must be carefully avoided when applying repellent. If using sunscreen, it should be applied before the repellent. Insect repellents should contain among their ingredients:

- DEET (N,N-diethyl-3-methylbenzamide or N,N-diethyl-m-toluamide), as in Off!, Cutter, Sawyer, or Ultrathon
- picaridin (2-[2-hydroxyethyl]-1-piperidinecarboxylic acid 1-methylpropyl ester), as in Cutter Advanced, Skin So Soft Bug Guard Plus, Autan outside the United States, and as KBR 3023 in Bayrepel
- oil of lemon eucalyptus (OLE) or the synthetic form PMD (para-menthane-3,8-diol), as in Repel and Off! Botanicals
- IR3535 (3-[N-butyl-N-acetyl]-aminopropionic acid, ethyl ester) as in Skin So Soft Bug Guard Plus Expedition and SkinSmart

Other measures for reducing exposure to mosquitoes and preventing additional mosquito bites that further spread the disease include:

- covering exposed skin with long sleeves, long pants, and hats
- residing and sleeping in screened or air-conditioned rooms
- using mosquito coils or other insecticide vaporizers indoors
- using a bed net if sleeping exposed to the outdoors
- removing standing water
- reducing natural and artificial breeding habitats in affected communities
- spraying insecticides and applying insecticides to surfaces and in and around water containers during outbreaks
- treating water to kill immature larvae
- supporting local vector control

Permethrin-treated clothing and gear, including boots and tents, can be used. Instructions should be followed carefully. The product information should indicate how many washings the treatment can survive. Permethrin should not be applied to the skin.

Healthcare providers should report suspected chikungunya cases to local or state health departments, both to confirm diagnosis and help reduce the risk of transmission. As of 2014, vaccines against chikungunya were in various stages of development.

Margaret Alic, PhD

Child abuse

Definition

Child **abuse**, sometimes called child maltreatment, describes four types of actions toward children: physical abuse, **sexual abuse**, psychological abuse, and neglect. In many cases, the same child experiences

Child abuse signs and symptoms

Although these signs do not necessarily indicate that a child has been abused, they may help adults recognize that something is wrong. The possibility of abuse should be investigated if a child shows a number of these symptoms, or any of them to a marked degree:

Sexual abuse

Being overly affectionate or knowledgeable in a sexual way inappropriate to the child's age
Medical problems such as chronic itching, pain in the genitals, or venereal diseases
Other extreme reactions, such as depression, self-mutilation, suicide attempts, running away, overdoses, or anorexia
Personality changes, such as becoming insecure or clingy
Regressing to younger behavior patterns such as thumb sucking or bringing out discarded cuddly toys
Sudden loss of appetite or engaging in compulsive eating
Being isolated or becoming withdrawn
Inability to concentrate
Lack of trust or fear toward someone they know well, such as not wanting to be alone with a babysitter or specific family member
Starting to wet the bed again or having nightmares
Anxiety about clothing being removed
Suddenly starting to draw sexually explicit pictures
Trying to be "ultra-good" or perfect; overreacting to criticism

Physical abuse

Unexplained recurrent injuries or burns
Improbable excuses or refusal to explain injuries
Wearing clothes to cover injuries, even in hot weather
Refusal to undress for gym
Bald patches
Chronic running away
Fear of medical help or examination
Self-destructive tendencies
Aggression toward others
Fear of physical contact; shrinking back if touched
Admitting that they are punished, but the punishment is excessive (such as a child being beaten every night to make him/her study)
Fear of suspected abuser being contacted

Psychological abuse

Physical, mental, and psychological developmental lags
Sudden speech disorders
Continual self-depreciation (e.g., "I'm stupid, ugly, worthless," etc.)
Overreaction to mistakes
Extreme fear of any new situation
Inappropriate response to pain (e.g., "I deserve this")
Neurotic behavior (e.g., rocking, hair twisting, self-mutilation)
Extremes of passivity or aggression

Neglect

Constant hunger
Poor personal hygiene
No social relationships
Constant tiredness
Poor state of clothing
Compulsive scavenging
Emaciation
Untreated medical problems
Destructive tendencies

A child may be subjected to a combination of different kinds of abuse. It is also possible that a child may show no outward signs and hide what is happening from everyone.

(Table by PreMediaGlobal. © Cengage Learning®.)

more than one type of abuse. The abusers can be parents or other family members, caregivers such as teachers or babysitters, acquaintances (including other children), and, in very rare instances, strangers.

Demographics

Child abuse was once viewed as a minor social problem in the United States. However, in the late twentieth century, issues of child welfare came under scrutiny by the media, law enforcement, and health-care professionals. This increase in awareness led to a sharp rise in the number of reported cases of child abuse. Today, child abuse is recognized as a problem that occurs among households of all racial, ethnic, and income levels, although the incidence of reported cases is higher in low-income households where adult caregivers experience greater financial stress and social difficulties, have less education and less understanding of child development, and may have less access to social services. In addition, children of parents who are substance abusers are more likely to experience abuse than children living in households where there is no substance abuse. Many child abusers were themselves abused as children.

Statistically, it is difficult to find reliable national figures for cases of child abuse because each state keeps its own records and has its own definitions of what constitutes abuse. Child abuse almost always occurs in private, and because abuse often is hidden from view and its victims may be too young or too frightened to speak out, experts suggest that its true prevalence is probably greater than official data indicates. The majority of children are abused by their parents, so the child may feel that they have no advocate for their well being. However, based on information reported by states to the U.S. Department of Health and Human Services Administration for Children and Families, in 2009, approximately 702,000 children were victims of child abuse. Of those, 78% were victims of neglect, 18% were physically abused, 10% suffered sexual abuse, 8% were psychologically or emotionally maltreated, 2% experienced medical neglect, and 10% suffered other types of abuse, including congenital drug **addiction** (existing at birth). An estimated 1,770 children died as a result of abuse or neglect.

Description

There are four types of child abuse: physical (intentional infliction of injury or **pain**), sexual (any sexual activity, even if there is no physical contact), psychological (verbal or emotional abuse), and neglect (failure to provide for the child's basic needs).

Physical abuse

Physical abuse is the nonaccidental infliction of physical injury to a child. Legal definitions of physical child abuse vary from state to state, but injuries requiring medical attention typically are regarded as abusive. Physical abuse takes many forms, including cuts, **bruises**, **burns**, broken bones, **poisoning**, and internal injuries. Nonetheless, difficulties associated with defining the line between discipline and abuse are well known. Many states explicitly note that spanking "when administered in a reasonable manner" does not constitute abuse. Thus, how severely parents can inflict physical punishment upon their children without it being considered abusive remains subject to interpretation.

The physical abuser is usually a family member or other caregiver and is likely to be male. The injuries can be inflicted by such actions as punching, kicking, biting, burning, or beating, or by use of a weapon such as a baseball bat or knife. A rare form of physical abuse is **Munchausen syndrome** by proxy, in which a caregiver (most often the mother) seeks attention by intentionally making the child sick or appear to be sick.

Sexual abuse

Children are sexually abused when they experience contact that is for the sexual gratification of an adult or a significantly older or dominant child when they are younger than the legal age of consent or at a stage of development at which they do not possess sufficient maturity to understand the nature of the acts and therefore to provide informed consent. Abusers may use coercion or deceptive manipulation, but often physical force is not necessary since the perpetrator is likely to be someone with whom the child has a trusting relationship and who is in a position of authority over the child. In many states, sexual activity is automatically assumed to be abuse when a defined age difference exists between the older abuser and the younger (minor) victim independent of any consent the victim may have given.

Sexual behaviors can include touching the breasts, genitals, and buttocks while the victim is either dressed or undressed. Sexually abusive behavior also includes cunnilingus, fellatio, or penetration of the vagina or anus with sexual organs or objects. However, sexual abuse does not have to involve any actual touching. Children can be coerced into disrobing and exposing themselves or watching adults disrobe or engage in sexual activity. Pornographic photography or videography also are forms of sexual abuse of children.

WWW.BOOKBAZ.IR

Sexual abuse victims can be either boys or girls, though most, but not all, perpetrators are male. Despite publicity surrounding cases where a child is sexually assaulted by a stranger, almost all sexual abuse against children is perpetrated by a family member (e.g. father, stepfather, aunt, uncle, sibling, cousin) or family intimate (e.g., live-in partner or friend of the parent). Perpetrators go to great lengths to conceal sexual abuse. Children who have been sexually abused may not report the behavior due to threats, shame, or to a lack of understanding of what has happened.

Rape is the most violent form of sexual abuse. An act of sexual intercourse is considered rape when

- will is overcome by force or fear, whether from threats, use of weapons, violence, or use of drugs;
- mental impairment renders the victim incapable of rational judgment; or
- the victim is below the legal age established for consent.

Psychological abuse

Abuse of children is not limited to the physical body. Psychological abuse encompasses rejecting, ignoring, criticizing, belittling, humiliating, threatening with violence, or otherwise terrorizing the child, all of which have the effect of eroding the child's self-esteem and sense of security. This type of abuse can also include isolating the child from friends or other family members or destroying the child's property.

Psychological abuse may be the result of actions not directed specifically at the child. The prevalence of domestic violence exposes children to intimidating and frightening scenes every day. Many children live in homes where domestic violence is an ongoing problem that they witness regularly, often as a result of being "caught in the middle" of a parental altercation. Children who observe violence react with many of the same psychological symptoms as children who have experienced it directly.

Psychological abuse often accompanies other types of abuse. It is difficult to prove and rarely is reported.

Neglect

Neglect is the failure to satisfy a child's basic needs and can assume many forms. Physical neglect is the failure (beyond the constraints imposed by poverty) to provide adequate food, clothing, shelter, or supervision. Children may live in filthy conditions or situations where food is not provided, or where they develop infections or other medical conditions that go untreated. Failure to send children to school or otherwise provide for their education may also be considered neglect. Psychological neglect is the failure to satisfy a child's normal psychological needs and/or behavior that damages a child's normal psychological development (e.g., permitting drug abuse in the home, having the child witness domestic violence).

Risk factors

The greatest risk factor for abuse is being young; the most child fatalities due to abuse or neglect are in children younger than age four. Children who are disabled and those who are nonrhythmic (have unpredictable eating and sleeping patterns) are also more likely to be abused. Similarly, children who are distractible, impulsive, or who have high activity levels are more likely to experience physical abuse.

Causes and symptoms

Causes

SOCIOCULTURAL FACTORS. Poverty is the sociocultural factor most strongly linked to abuse. Although physical abuse occurs at all income levels, it happens more often in very poor families. It is possible that abuse in middle- and upper-class families is less likely to be reported or recognized by an outside source, such as a family physician, than abuse in poorer families, where the abuse may be realized when the victim is treated in an emergency room or public clinic setting. Even with such reporting bias, however, poverty seems strongly linked to abuse, possibly due to the frustrating effects of poverty on the parents. Physical crowding is also associated with abuse, a condition more likely to occur in poverty. If too many people share a small living space, severe punishment of children as a means of maintaining control is more likely.

Job loss and dissatisfaction are other factors often associated with child abuse. Higher rates of abuse exist in military compared to non-military families. It is generally felt that the link between these environmental stressors and abuse is strengthened by the absence of social support networks that might otherwise buffer the family against adversity. Having no one to assist with child care or no one to question the use of severe discipline increases the chance that a parent may injure a child.

Perpetrators of sexual abuse in children, or pedophiles, exist in all economic and cultural groups. Psychologically, however, they share certain traits. Pedophiles often have a history of being abused themselves, and abusing other children seems to be triggered

by increased life stressors such as marital problems, job layoffs, or abuse of drugs.

CAREGIVER FACTORS. Parents who abuse their children are likely to be younger than the average parent and are more likely to be single parents. Having a mental illness, such as depression, or abusing drugs or alcohol also makes a parent more likely to abuse his or her child. Parents who were themselves abused as children are more likely to abuse their own children, though not every parent who was abused becomes an abuser; some parents go to great lengths to ensure that they never harm their children.

Abusive parents socialize differently from nonabusive parents. Nonabusive parents tend to use ignoring or time-out procedures, whereas abusive parents tend to shout, threaten, and spank. Some forms of child abuse escalate over time, with the parent spanking harder and more frequently to get the same effect or resorting to abuse to get results. Female caregivers inflict more soft tissue injuries, broken bones, and internal injuries than male caregivers. Severe injuries from a single, explosive incident in which the child is shaken, thrown, or struck are more likely to involve male caregivers.

Abusive parents often expect their children to perform behaviors that they are not yet capable of performing. Parents who abuse young children expect them to be able to control their impulses, recall and obey complex parental rules, and perform mature chains of behavior such as getting up, washing, and getting dressed by themselves. Nonabusive parents recognize that toddlers and preschool children are incapable of such behaviors. Understanding the limitations of a young child's memory, ability to follow instructions, impulse control, and attention span is essential to developing reasonable expectations for the child. Parents who expect behavior a child cannot deliver are apt to progressively increase their control techniques in order to get the child to comply.

Abusive discipline is often the result of the belief that the young child is deliberately misbehaving to cause the parent difficulty. Parents who adopt this belief make claims such as that their 18-month-old could stay clean if she wanted to but dirties her clothing just to make more work for the mother. Abusive parents who believe a child has chosen to misbehave inflict more punishment on their children than parents who accurately recognize when a child's behavior is not intentional. Such abusive parents believe that effective parenting involves maintaining tight control over the child, which is often linked to the application of force.

Another belief abusive parents often hold is that their children should engage in reciprocal parenting. They believe that if they sometimes comfort, wait on, and take care of the child, the child should do the same for them. Such beliefs stem from the abusive parents' lack of awareness of children's developmental capabilities and possibly the parents' own immaturity or lack of support from other adults. Regardless of the source, when such expectations are not met by the child, the parent often responds with anger and hostility.

EMOTIONAL FACTORS. Anger is the most frequent trigger for parental abuse. Abusive parents appear to have a lower threshold for childish behaviors than average parents. Thus, child behaviors that are merely irritating to average parents are infuriating to abusive parents. Finally, abusive parents may have less control over their anger than nonabusive parents, either because they are unaware of their level of anger, because they are chronically angry, or because they lack **anger management** skills.

When considering how emotion influences child abuse, it seems important to consider positive emotions as well. Abusive parents consider their children less rewarding than nonabusive parents. In observation, abusive parents touch their children less, cuddle them less, less frequently call the affectionate names ("honey," "sweetheart"), and smile less at their children. Nonabusive parents respond flexibly to their children, letting the child lead the play interaction. Even in play, abusive parents have expectations that their children seem unable or unwilling to fulfill, making play a disagreeable chore rather than a rewarding endeavor. Abusive parents seem trapped by their own lack of skills, limited developmental understanding, inappropriate expectations, high negative emotion, and low enjoyment of the child.

Symptoms

Although these signs do not necessarily indicate that a child has been abused, they may help adults recognize that something is wrong. The possibility of abuse should be investigated if a child shows a number of these symptoms, or any of them to a marked degree.

Physical abuse:

- unexplained recurrent injuries or burns
- improbable excuses or refusal to explain injuries
- wearing clothes to cover injuries, even in hot weather
- refusal to undress for gym
- bald patches
- chronic running away

WWW.BOOKBAZ.IR

- fear of medical help or examination
- self-destructive tendencies
- aggression toward others
- fear of physical contact; shrinking back if touched
- admitting excessive punishment (such as a child being beaten every night to make him/her study)
- fear of suspected abuser being contacted

Sexual abuse:

- overly affectionate or knowledgeable in a sexual way inappropriate to the child's age
- medical problems such as chronic itching, pain in the genitals, venereal diseases
- development of depression, self-mutilation, suicide attempts, overdoses, anorexia, or other severe actions
- attempts at running away
- personality changes such as becoming insecure or clingy
- regressing to younger behavior patterns such as thumb-sucking or bringing out discarded cuddly toys
- sudden loss of appetite or engaging in compulsive eating
- social isolation or withdrawal
- inability to concentrate
- lack of trust or fear for someone they know well, such as not wanting to be alone with a babysitter or specific family member
- anxiety about clothing being removed
- wetting the bed or having nightmares
- drawing sexually explicit pictures
- trying to be "ultra-good" or perfect; overreacting to criticism

Psychological abuse:

- physical, mental, and psychological developmental lags
- sudden speech disorders
- continual self-depreciation (e.g.,"I'm stupid, ugly, worthless," etc.)
- overreaction to mistakes
- extreme fear of any new situation
- inappropriate response to pain (e.g., "I deserve this")
- neurotic behavior (e.g., rocking, hair twisting, self-mutilation)
- extremes of passivity or aggression

Neglect:

- constant hunger
- poor personal hygiene
- no social relationships
- constant tiredness
- poor state of clothing
- compulsive scavenging
- emaciation
- untreated medical problems
- destructive tendencies

A child may be subjected to a combination of different kinds of abuse. It is also possible that a child may show no outward signs and hide what is happening from everyone.

Diagnosis

Doctors and many other professionals who work with children are required by law to report suspected abuse to their state's Child Protective Services (CPS) agency. Abuse investigations often are a group effort involving medical personnel, social workers, police officers, and others. Some hospitals and communities maintain child protection teams that respond to cases of possible abuse. Careful questioning of the parents is crucial, as is interviewing the child (if he or she is capable of being interviewed). Trained investigators must ensure, however, that their questioning does not further traumatize the child and also that their style of questioning does not prompt the child to give the answers the child thinks the questioner wants rather than accurate answers. A **physical examination** for signs of physical or sexual abuse or of neglect is necessary and may include x rays, blood tests, and other procedures.

Treatment

Notification of the appropriate authorities, treatment of the child's injuries, and protecting the child from further harm are the immediate priorities in abuse cases. If the child does not require hospital treatment, protection often involves placing him or her with relatives, in a group home, or in foster care. Once the immediate concerns are dealt with, it becomes essential to determine how the child's long-term medical, psychological, educational, and other needs can best be met. This process involves evaluating not only the child's needs but also the needs of the family (e.g., drug abuse counseling, parental skills training, anger management training). The authorities also must determine whether other children living in the same household have been abused. On investigation, signs of physical abuse are discovered in about 20% of other children living in the abused child's household.

Prognosis

Child abuse often has lifelong consequences. Research shows that abused children and adolescents are more likely to do poorly in school and experience depression, extreme anger, antisocial personality traits, and other psychiatric problems. They also are more likely to become promiscuous, abuse drugs and alcohol, run away, and attempt **suicide**. As adults, they often have trouble establishing intimate relationships.

Most children who have been abused experience some symptoms of **post-traumatic stress disorder** (PTSD). PTSD in children and adolescents may be acute or delayed, meaning that the child may experience symptoms immediately or not until after a period of time has passed, perhaps when the child feels safe. Symptoms may include re-experiencing the abusive episodes at some level, feeling emotionally numb, or feeling the physiological effects of fear (elevated heart rate, abnormal breathing patterns, and so forth). Children may experience disassociation and appear to "space out" when reminded of the abuse or perpetrator. They may become enraged or feel guilt at having provoked the episodes or survived them. They may have invasive memories, repeated behaviors, or fears related to the abusive situations. They may act out some of their issues in play—punishing the bad guy or victimizing another character when playing with dolls or action figures. In severe cases of chronic **trauma**, the child may develop serious or prolonged disassociation or depression. Severe and chronic abuse has also been implicated in cases of **multiple personality disorder**.

Once the abuse has stopped, some of these symptoms can be treated with some form of counseling or therapy, but full recovery may be a lifelong task. Adults who have been abused as children may have to face issues long after the abuse has stopped, such as when they enter into sexual relationships or when they raise their own children. Long-term therapy by a professional trained in working with abused children and adults offers the best chance of overcoming childhood abuse.

Prevention

There are many barriers to changing abusive parental behavior. Most abusive parents' own histories suggest that strong physical discipline is the preferred model of parenting, and most abusive parents live in families and neighborhoods in which violence is not only condoned but viewed as a necessary vehicle for interpersonal influence. The stressors that are omnipresent in abusive parents' lives contribute to high levels of anger and depression, which prevent the parent from experiencing enjoyment of the child. Further, when a parent responds with strong physical discipline, the child's misbehavior typically stops, at least for that moment, reinforcing the parent's behavior.

It may be preferable to prevent the development of abusive parenting by instituting early interventions to provide parental skills, alter developmental knowledge, change unreasonable parenting expectations, and block the steady build-up of anger and extinguishing of affection for the child. Prevention programs now target teenagers before **pregnancy** as well as young mothers to try to break the cycle of abuse.

Government efforts to prevent abuse include home-visitor programs aimed at high-risk families and school-based efforts to teach children how to respond to attempted sexual abuse. Psychological abuse prevention has been promoted through the media.

When children reach age three, parents should begin teaching them about "bad touches" and about confiding in a suitable adult if they are touched or treated in a way that makes them uneasy. Parents also need to **exercise** caution in hiring babysitters and other caregivers. Anyone who suspects abuse should report those suspicions to the police or his or her local CPS agency. Prevent Child Abuse America (listed in references) is an excellent source of information on the many support groups and other organizations that help abused and at-risk children and their families. One of these organizations, Parents Anonymous, sponsors local self-help groups throughout the United States, Canada, and Europe.

Childbirth

Definition

Childbirth includes both labor (the process of birth) and delivery (the birth itself); it refers to the entire process as an infant makes its way from the womb down the birth canal to the outside world.

Description

Childbirth usually begins spontaneously, about 280 days after conception, but it may be started by artificial means if the **pregnancy** continues past 42 weeks gestation. The average length of labor is about 14 hours for a first pregnancy and about eight hours in subsequent pregnancies. However, many women experience a much longer or shorter labor.

Labor can be described in terms of a series of phases.

First stage of labor

During the first phase of labor, the cervix dilates (opens) from 0–10 cm. This phase has an early, or latent, phase and an active phase. During the latent phase, progress is usually very slow. It may take quite a while and many contractions before the cervix dilates the first few centimeters. Contractions increase in strength as labor progresses. Most women are relatively comfortable during the latent phase and walking around is encouraged, since it naturally stimulates the process.

As labor begins, the muscular wall of the uterus begins to contract as the cervix relaxes and expands. As a portion of the amniotic sac surrounding the baby is pushed into the opening, it bursts under the pressure, releasing amniotic fluid. This is called "breaking the bag of waters."

During a contraction, the infant experiences intense pressure that pushes it against the cervix, eventually forcing the cervix to stretch open. At the same time, the contractions cause the cervix to thin. During this first stage, a woman's contractions occur more and more often and last longer and longer. The doctor or nurse will do a periodic **pelvic exam** to determine how the mother is progressing. If the contractions aren't forceful enough to open the cervix, a drug may be given to make the uterus contract.

As **pain** and discomfort increase, women may be tempted to request pain medication. If possible, though, administration of pain medication or anesthetics should be delayed until the active phase of labor begins—at which point the medication will not act to slow down or stop the labor.

The active stage of labor is faster and more efficient than the latent phase. In this phase, contractions are longer and more regular, usually occurring about every two minutes. These stronger contractions are also more painful. Women who use the breathing exercises learned in childbirth classes find that these can help cope with the pain experienced during this phase. Many women also receive some pain medication at this point—either a short-term medication, such as Nubain or Numorphan, or an epidural **anesthesia**.

As the cervix dilates to 8–9 cm, the phase called the transition begins. This refers to the transition from the first phase (during which the cervix dilates from 0–10 cm) and the second phase (during which the baby is pushed out through the birth canal). As the baby's head begins to descend, women begin to feel the urge to "push" or bear down. Active pushing by the mother should not begin until the second phase, since pushing too early can cause the cervix to swell or to tear and bleed. The attending healthcare practitioner should counsel the mother on when to begin to push.

Second stage of labor

As the mother enters the second stage of labor, her baby's head appears at the top of the cervix. Uterine contractions get stronger. The infant passes down the vagina, helped along by contractions of the abdominal muscles and the mother's pushing. Active pushing by the mother is very important during this phase of labor. If an epidural anesthetic is being used, many practitioners recommend decreasing the amount administered during this phase of labor so that the mother has better control over her abdominal muscles

When the top of the baby's head appears at the opening of the vagina, the birth is nearing completion. First the head passes under the pubic bone. It fills the lower vagina and stretches the perineum (the tissues between the vagina and the rectum). This position is called "crowning," since only the crown of the head is

visible. When the entire head is out, the shoulders follow. The attending practitioner suctions the baby's mouth and nose to ease the baby's first breath. The rest of the baby usually slips out easily, and the umbilical cord is cut.

Episiotomy

As the baby's head appears, the perineum may stretch so tight that the baby's progress is slowed down. If there is risk of tearing the mother's skin, the doctor may choose to make a small incision into the perineum to enlarge the vaginal opening. This is called an **episiotomy**. If the woman has not had an epidural or pudendal block, she will get a local anesthetic to numb the area. Once the episiotomy is made, the baby is born with a few pushes.

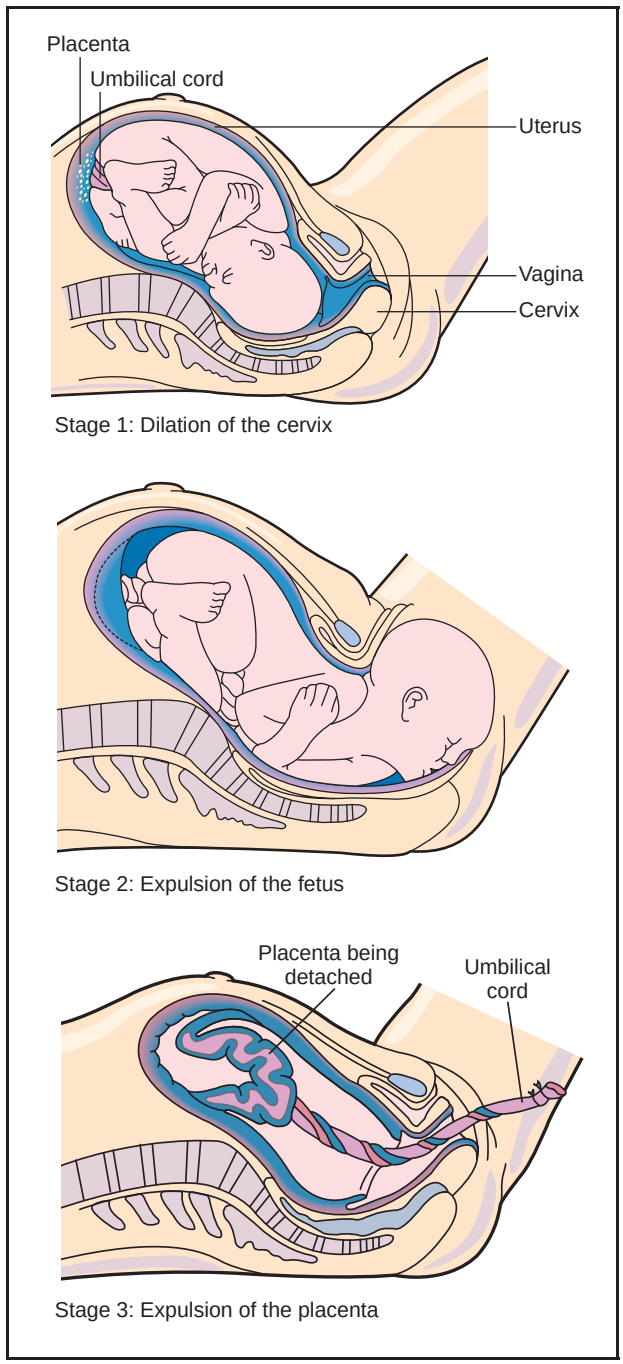
Third stage

In the final stage of labor, the placenta is pushed out of the vagina by the continuing uterine contractions. The placenta is pancake shaped and about 10 inches in diameter. It has been attached to the wall of the uterus and has served to convey nourishment from the mother to the fetus throughout the pregnancy. Continuing uterine contractions cause it to separate from the uterus at this point. It is important that all of the placenta be removed from the uterus. If it is not, the uterine bleeding that is normal after delivery may be much heavier.

Breech presentation

Approximately 4% of babies are in what is called the "breech" position when labor begins. In breech presentation, the baby's head is not the part pressing against the cervix. Instead the baby's bottom or legs are positioned to enter the birth canal instead of the head. An obstetrician may attempt to turn the baby to a head down position using a technique called version. This is only successful approximately half the time.

The risks of vaginal delivery with breech presentation are much higher than with a head-first presentation. The mother and attending practitioner will need to weigh the risks and make a decision on whether to deliver via a **cesarean section** or attempt a vaginal birth. The extent of the risk depends to a great extent on the type of breech presentation, of which there are three. Frank breech (the baby's legs are folded up against its body) is the most common and the safest for vaginal delivery. The other types are complete breech (in which the baby's legs are crossed under and in front of the body) and footling breech (in which one leg or both legs are positioned to enter the birth canal). These are not considered safe to attempt vaginal delivery.



Stage 1: Dilation of the cervix. Stage 2: Expulsion of the fetus. Stage 3: Expulsion of the placenta. *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

Even in complete breech, other factors should be met before considering a vaginal birth. An **ultrasound** examination should be done to be sure the

WWW.BOOKBAZ.IR

baby does not have an unusually large head and that the head is tilted forward (flexed) rather than back (hyperextended). Fetal monitoring and close observation of the progress of labor are also important. A slowing of labor or any indication of difficulty in the body passing through the pelvis should be an indication that it is safer to consider a cesarean section.

Forceps delivery

If the labor is not progressing as it should or if the baby appears to be in distress, the doctor may opt for a forceps delivery. A forceps is a spoon-shaped device that resembles a set of salad tongs. It is placed around the baby's head so the doctor can pull the baby gently out of the vagina.

Forceps can be used after the cervix is fully dilated, and they might be required if:

- the umbilical has dropped down in front of the baby into the birth canal
- the baby is too large to pass through the birth canal unaided
- the baby shows signs of stress
- the mother is too exhausted to push

Before placing the forceps around the baby's head, pain medication or anesthesia may be given to the mother. The doctor may use a catheter to empty the mother's bladder, and may clean the perineal area with soapy water. Often an episiotomy is done before a forceps birth, although tears can still occur.

The obstetrician slides half of the forceps at a time into the vagina and around the side of the baby's head to gently grasp the head. When both "tongs" are in place, the doctor pulls on the forceps to help the baby through the birth canal as the uterus contracts. Sometimes the baby can be delivered this way after the very next contraction.

The frequency of forceps delivery varies from one hospital to the next, depending on the experience of staff and the types of anesthesia offered at the hospital. Some obstetricians accept the need for a forceps delivery as a way to avoid cesarean birth. However, other obstetrical services do not use forceps at all.

Complications from forceps deliveries can occur. Sometimes they may cause nerve damage or temporary **bruises** to the baby's face. When used by an experienced physician, forceps can save the life of a baby in distress.

Vacuum-assisted birth

This method of helping a baby out of the birth canal was developed as a gentler alternative to forceps. Vacuum-assisted birth can only be used after the cervix is fully dilated (expanded), and the head of the fetus has begun to descend through the pelvis. In this procedure, the doctor uses a device called a vacuum extractor, placing a large rubber or plastic cup against the baby's head. A pump creates suction that gently pulls on the cup to ease the baby down the birth canal. The force of the suction may cause a bruise on the baby's head, but it fades away in a day or so.

The vacuum extractor is not as likely as forceps to injure the mother, and it leaves more room for the baby to pass through the pelvis. However, there may be problems in maintaining the suction during the vacuum-assisted birth, so forceps may be a better choice if it is important to remove the baby quickly.

Cesarean sections

A cesarean section, also called a c-section, is a surgical procedure in which incisions are made through a woman's abdomen and uterus to deliver her baby.

Cesarean sections are performed whenever abnormal conditions complicate labor and vaginal delivery, threatening the life or health of the mother or the baby. In 2002, just over 26% of babies were born by c-section, an increase of 7% from the previous year. The procedure may be used in cases where the mother has had a previous c-section and the area of the incision has been weakened. Dystocia, or difficult labor, is the another common reason for performing a c-section.

Difficult labor is commonly caused by one of the three following conditions: abnormalities in the mother's birth canal; abnormalities in the position of the fetus; abnormalities in the labor, including weak or infrequent contractions.

Another major factor is fetal distress, a condition where the fetus is not getting enough oxygen. Fetal brain damage can result from oxygen deprivation. Fetal distress is often related to abnormalities in the position of the fetus, or abnormalities in the birth canal, causing reduced blood flow through the placenta.

Other conditions also can make c-section advisable, such as vaginal herpes, **hypertension** (high blood pressure), and diabetes in the mother. Some parents

choose to have a c-section because they fear the pain or unpredictability of labor or they want to avoid pelvic damage.

Causes and symptoms

One of the first signs of approaching childbirth may be a "bloody show," the appearance of a small amount of blood-tinged mucus released from the cervix as it begins to dilate. This is called the "mucus plug."

The most common sign of the onset of labor is contractions. Sometimes women have trouble telling the difference between true and false labor pains.

True labor pains:

- develop a regular pattern, with contractions coming closer together
- last from 15–30 seconds at the onset and get progressively stronger and longer (up to 60 seconds)
- may get stronger with physical activity
- occur high up on the abdomen, radiating throughout the abdomen and lower back

Another sign that labor is beginning is the breaking of the "bag of waters," the amniotic sac which had cushioned the baby during the pregnancy. When it breaks, it releases water in a trickle or a gush. Only about 10% of women actually experience this water flow in the beginning of labor, however. Most of the time, the rupture occurs sometime later in labor. If the amniotic sac doesn't rupture on its own, the doctor will break it during labor.

Some women have **diarrhea** or nausea as labor begins. Others notice a sudden surge of energy and the urge to clean or arrange things right before labor begins; this is known as "nesting."

Diagnosis

The onset of labor can be determined by measuring how much the cervix has dilated. The degree of dilation is estimated by feeling the opening cervix during a pelvic exam. Dilation is measured in centimeters, from zero to 10. Contractions that cause the cervix to dilate are the sign of true labor.

Fetal monitoring

Fetal monitoring is a process in which the baby's heart rate is monitored for indicators of **stress** during labor and birth. There are several types of fetal monitoring.

A special stethoscope called a fetoscope may be used. This is a simple and non-invasive method.

The Doppler method uses ultrasound; it involves a handheld listening device that transmits the sounds of the heart rate through a speaker or into an attached ear piece. It can usually pick up the heart sounds 12 weeks after conception. This method offers intermittent monitoring. It allows the mother freedom to move about and is also useful during contractions.

Electronic fetal monitoring uses ultrasound and provides a view of the heartbeat in relationship to the mother's contractions. It can be used either continuously or intermittently. It is often used in high risk pregnancies, and is not often recommended for low risk ones because it renders the mother immobile and requires interpretation.

Internal monitoring does not use ultrasound, is more accurate than electronic monitoring and provides continuous monitoring for the high risk mother. This requires the mother's water to be broken and that she be two to three centimeters dilated. It is used in high-risk situations only.

Telemetry monitoring is the newest type of monitoring. It uses radio waves transmitted from an instrument on the mother's thigh. The mother is able to remain mobile. It provides continuous monitoring and is used in high-risk situations.

Treatment

Most women choose some type of pain relief during childbirth, ranging from relaxation and imagery to drugs. The specific choice may depend on what's available, the woman's preferences, her doctor's recommendations, and how the labor is proceeding. All drugs have some risks and some advantages.

Regional anesthetics

Regional anesthetics include epidurals and spinals. In this technique, medication is injected into the space around the spinal nerves. Depending on the type of medications used, this type of anesthesia can block nerve signals, causing temporary pain relief, or a loss of sensation from the waist down. An epidural or spinal block can provide complete pain relief during cesarean birth.

An epidural is placed with the woman lying on her side or sitting up in bed with the back rounded to allow more space between the vertebrae. Her back is scrubbed with antiseptic, and a local anesthetic is injected in the skin to numb the site. The needle is inserted between two vertebrae and through the tough tissue in front of the spinal column. A catheter is put in place that allows continuous doses of anesthetic to be given.

WWW.BOOKBAZ.IR

KEY TERMS

Amniotic sac—The membranous sac that surrounds the embryo and fills with watery fluid as pregnancy advances.

Breech birth—Birth of a baby bottom-first, instead of the usual head first delivery. This can add to labor and delivery problems because the baby's bottom doesn't mold a passage through the birth canal as well as does the head.

Cervix—A small cylindrical organ about an inch or so long and less than an inch around that makes up the lower part and neck of the uterus. The cervix separates the body and cavity of the uterus from the vagina.

Embryo—The unborn child during the first eight weeks of its development following conception.

Gestation—The period from conception to birth, during which the developing fetus is carried in the uterus.

Perineum—The area between the thighs that lies behind the genital organs and in front of the anus.

Placenta—The organ that develops in the uterus during pregnancy and that links the blood supplies of mother and baby.

This type of anesthesia provides complete pain relief, and can help conserve a woman's energy, since she can relax or even sleep during labor. This type of anesthesia requires an IV and fetal monitor. It may be harder for a woman to bear down when it comes time to push, although the amount of anesthesia can be adjusted as this stage nears.

Spinal anesthesia operates on the same principle as epidural anesthesia, and is used primarily in cases of c-section delivery. It is administered in the same way as an epidural, but the catheter is not left in place. The amount of anesthetic injected is large, since it must be injected at one time. Because of the anesthetic's effect on motor nerves, most women using it cannot push during delivery. This is a disadvantage in labor, but not an issue during a c-section. Spinals provide quick and strong anesthesia and allow for major abdominal surgery with almost no pain.

Narcotics

Short-acting **narcotics** can ease pain and do not interfere with a woman's ability to push. However, they can cause **sedation**, **dizziness**, nausea, and **vomiting**. Narcotics cross the placenta and may slow down a baby's breathing; they can't be given too close to the time of delivery.

Natural childbirth and preparation for childbirth

There are several methods to prepare for childbirth. The one selected often depends on what is available through the healthcare provider. Overall, family involvement is receiving increased attention by the healthcare systems, and many hospitals now offer birthing rooms and maternity centers to help the entire family. There are several choices available for childbirth preparation.

Lamaze, or Lamaze-Pavlov, is the most common in the United States today. It was the first popular natural childbirth method, becoming popular in the 1960s. Breathing exercises and concentration on a focal point are practiced to allow mothers to control pain while maintaining consciousness. This allows the flow of oxygen to the baby and to the muscles in the uterus to be maintained. A partner coaches the mother throughout the birthing process.

The Read method, named for Dick Read, is a technique of breathing that was originated in the 1930s to help mothers deal with apprehension and tension associated with childbirth. This natural childbirth method uses different breathing for the different stages of childbirth.

The LeBoyer method stresses a relaxed delivery in a quiet, dim room. It attempts to avoid overstimulation of the baby and to foster mother-child bonding by placing the baby on the mother's abdomen and having the mother massage him or her immediately after the birth. Then the father washes the baby in a warm bath.

The Bradley method is called father-coached childbirth, because it focuses on the father serving as coach throughout the process. It encourages normal activities during the first stages of labor.

Childhood nutrition

Definition

Childhood **nutrition** concerns the dietary needs of children ages 2 through 11. Children younger than 2 and older than 11 have different nutritional requirements and concerns. Parents of children with special health needs or dietary restrictions require individualized diet advice. They should consult a pediatrician or a registered dietitian about their child's diet.

Description

Childhood is a time where many food likes and dislikes are determined, largely based on what food choices the family makes, socioeconomic status, budget, cultural or religious experiences, time constraints, and other various factors. The food environment in which a child is raised has a significant effect on food choices later in life. Parents, guardians, and others need to pay special attention to nutrition and food choices to support a wide variety of tastes and preferences.

Healthy eating habits in childhood have been shown to prevent chronic undernutrition and physical and cognitive growth problems as well as nutritional concerns such as iron-deficiency anemia and dental cavities. A healthy diet in childhood can help prevent **obesity** and weight-related diseases, such as type 2 diabetes, which is increasingly diagnosed in children in the United States.

USDA guidelines and MyPlate

In 1980, the first edition of *Dietary Guidelines for Americans* was released by the U.S. Department of Agriculture (USDA). This resource was intended to be updated repeatedly; the 2013 edition was destined to appear in revised form in 2015. *Dietary Guidelines for Americans* was developed specifically to help combat the increasing obesity problem in the United States. It focuses on providing recommendations that are easy for busy people to put into practice in their daily lives.

Some general guidelines from the 2013 directive include making sure children and adults abide by the following:

- Enjoy food, but eat less.
- Avoid oversized portions.
- Make half of the plate fruits and vegetables.
- Drink water instead of sugary drinks.
- Switch to fat-free or low-fat milk.

The 2013 guidelines include a wide variety of other recommendations. The two overarching themes of the recommendations are: (1) maintain calorie balance over time to achieve and sustain a healthy weight, and (2) focus on consuming nutrient-dense foods and beverages. Out of these guidelines the USDA developed and introduced MyPlate, which replaced the food pyramid. MyPlate offers a visual for families to create a nutritional plate for each meal based on dividing a plate into roughly 30% grains; 30% vegetables; 20% fruits; and 20% protein. A smaller circle separate from the plate represents a dairy product, such as a glass of milk or milk-based pudding.

Although MyPlate's general recommendations apply to almost all age groups, there are also suggestions for specific groups, including infants, preschoolers, and children. These suggestions include information about specific food groups, as well as suggested menus and tips for improving eating habits. Some general guidelines for kids ages 2–11 are:

- Making half of each plate fruits and vegetables. Kids 2–11 years old should have about 1–1.5 cups fruit and 1–2 cups vegetables per day.
- Switching to skim or 1% milk. Kids 2–11 years old should have 2–3 8-ounce glasses per day.
- Making at least half of all grains consumed whole grains. Kids 2–11 years old should have about 3–6 one-ounce equivalents of grains per day.
- Varying protein food choices. Kids 2–11 years old should have about 2–5 one-ounce equivalents of meat or meat substitutes per day.

WWW.BOOKBAZ.IR

- Choosing foods and drinks with little or no added sugars.
- Looking out for salt (sodium) in foods.
- Eating fewer foods that are high in solid fats.

School lunches

Once children enter school, parents need to either pack healthy lunch choices or make sure children receive healthy food at school. In the early 2000s, a major emphasis was placed on improving the nutritional value of lunch choices in schools. Schools generally offer balanced lunches, but many also offer snack bars or vending machines with sodas and snacks with high levels of sugar, fat, and **sodium**. Many teens choose these snacks over prepared school lunches. Nutrition experts have worked with educators to present adolescents with healthier choices at school, to decrease or change the messages of food advertising, and to better educate students in the classroom about good nutritional choices. Federal guidelines have been implemented to improve the nutritional value of the National School Lunch Program.

Purpose

Proper nutrition for a healthy child should provide sufficient essential nutrients, fiber, and energy (calories) to maintain normal growth, maximize cognitive development, and promote health. **Diets** should be balanced so that foods rich in some nutrients do not displace foods that are rich in other nutrients. It is also important that so low-nutrient foods (s-called empty calories) do not displace nutrient-dense foods. A child's diet should provide sufficient energy for proper physical and mental growth and development while preventing excess weight gain. The hope is to establish positive eating habits that continue into adulthood.

Precautions

The USDA guidelines are based on current research by nutrition scientists and are widely accepted by health professionals. For healthy children, there are no perceived precautions or risks associated with following these guidelines. Children younger than 2 or older than 11 should follow the recommendations for their particular age group. Children of any age who have special health concerns or dietary restrictions may not be able to adhere to the USDA guidelines and should follow the advice of their pediatrician or a registered dietitian (RD). The guidelines also assume that children have about 30 minutes of moderate physical activity per day. Children who have much more or much less might need adjustments in recommended amounts of some foods.

Complications

In addition to addressing children's energy needs, the guidelines take into consideration the need for specific nutrients to avoid the development of undernutrition or **malnutrition**. For example, adequate intake of **calcium** and **vitamin D** in children helps build strong bones and is a preventative measure against osteopenia and **rickets** (and later in life, **osteoporosis**). Adequate calcium and vitamin D intake is crucial during adolescence and early adulthood to reach peak bone mass. Failure of children to meet the requirements, in combination with a sedentary lifestyle, makes growth and strong bone development more difficult to achieve. Recommendations include several servings a day of low-fat or nonfat milk and dairy products (such as yogurt) in a child's diet.

Iron deficiency has negative effects on children's cognitive development and can affect their capacity to concentrate and do well in school. Adequate intake of foods containing iron, such as meats, pulses such as beans and lentils, and fortified breakfast cereals, help ensure that iron requirements are met.

While nutrient intake is important, overconsumption of nutrients can cause other problems. High saturated-fat intake is associated with increased low-density lipoprotein (LDL), the commonly labeled bad **cholesterol**, in childhood. This can increase the risk later in life of cardiovascular disease and type 2 diabetes. A diet that includes lean meats (e.g., skinless chicken breasts) and low-fat or nonfat dairy products and limits foods high in saturated fat can help implement healthy habits and decrease a child's risk of developing type 2 diabetes or cardiovascular disease later in life.

Obesity rates among children continue to rise, despite efforts of dieticians, pediatricians, and policymakers. The obesity rate in children ages 6 through 11 rose from 7% in 1980 to 17% in 2014, according to the Centers for Disease Control and Prefention. Research has found that children who are obese experience psychological **stress**, decreased **body image** scores, and lower self-esteem than normal weight children of the same age.

Obese children also are more likely to have health problems related to their obesity and to have obesity as teens and adults compared with normal-weight children. This condition increases their risk in later life of cardiovascular disease, **hypertension**, type 2 diabetes, non-alcoholic fatty **liver disease**, gallbladder disease,

KEY TERMS

Cholesterol—A waxy substance made by the liver and acquired through diet. High levels in the blood may increase the risk of cardiovascular disease.

Fiber—Also known as roughage or bulk. Insoluble fiber moves through the digestive system almost undigested and gives bulk to stools. Soluble fiber dissolves in water and helps keep stools soft.

Hypertension—Persistently high blood pressure.

Osteoarthritis—The most common form of arthritis, characterized by erosion of the cartilage layer that lies between the bones in weight-bearing joints. It occurs mainly in older people.

Type 2 diabetes—In this form of diabetes, either the pancreas does not make enough insulin or cells become insulin resistant and do not use insulin efficiently. Formerly only seen in adults, it is becoming increasingly common in overweight children and young adults.

osteoarthritis, and some cancers. Childhood nutritional guidelines emphasize nutrient-dense foods that provide enough calories for growth and activity while limiting foods and drinks of low nutritional value and high calorie content to avoid these health issues.

Parental concerns

Before children are two, parents' focus is on making sure their infant or toddler is consuming enough calories and nutrients to support growth and development. As the child ages, a shift occurs, and parents become more focused on the types of food their child is eating. There is a transition from the higher-fat foods needed in infancy to the lower or nonfat versions. During this time, children are highly influenced by flavor and will be guided to eat foods for taste instead of nutrition content, so parents need to be aware of what their children are eating and should limit foods high in fat and added sugar. Parents are also responsible for making sure that the foods offered are safe and appropriate for the child and their developmental skills.

For parents, childhood can be a time of quarrels over food as their child is becoming more independent in eating behavior. When children are young, parents are responsible for what, when, and where the child eats. It is important that parents be attentive to the nutritional needs of their children and ensure that they are supplying appropriate foods in amounts that meet nutritional requirements. For younger children, having a set schedule of meal and snack times may help achieve nutritional balance. Parents should work with their children to teach them to recognize true hunger and develop healthy snacking habits. They also should not force their children to eat.

As habits are being formed during these years, it is important for meals and snacks to be a social and a pleasant time. Televisions, video games, and other distractions should be avoided at meal times. Eating the healthy foods as part of family meals and encouraging children to try new foods helps provide a model of healthy eating. Parents should not use food as a reward for good behavior, as a bribe, or for entertainment.

Children with **food allergies**, intolerances, or other medical concerns may display poor growth, poor eating skills, inadequate food intake, developmental delays, elimination problems, or metabolic disorders. A parent who is concerned about their child's health should consult a pediatrician. If a problem is found to be related to the child's diet, a referral to a specialist is important for early intervention so that it will not affect long-term growth and health.

Childhood obesity

Definition

Childhood **obesity** is the condition of being severely overweight between the ages of two and 19 years. The U.S. Centers for Disease Control and Prevention defines overweight as "having an excess body weight for a particular height." The excess weight can come from bone, fat, muscle, water, or a combination of all four. Obesity is defined as "having excess body fat."

Description

Childhood obesity is of increasing concern as a **public health** problem in the United States. Most healthcare professionals calculate obesity using the **body mass index** (BMI). BMI is a calculation that compares a person's weight and height to arrive at a specific number.

BMI for children is calculated the same way it is for adults, but, unlike for adults, age and gender are taken into consideration. The BMIs of children between the ages of two and 19 are compared against growth charts based on age and gender, referred to as BMI-for-age percentiles. A child's percentile indicates how his or her weight compares to other children who are the same age and gender. For example, if a boy is in the 65th percentile for his age group, 65 of every 100 children who are his age weigh less than he does and 35 of every 100 weigh more than he does.

The BMI weight categories for children are:

- below the 5th percentile: underweight
- 5th to less than the 85th percentile: healthy weight
- 85th to less than the 95th percentile: overweight
- 95th percentile and above: obese

In the early 2000s, many health organizations avoided applying the term "obese" to children. Children between the 85th and 95th percentile were classified as "at risk for overweight" and children above the 95th percentile were called "overweight." No child was labeled obese, in part because of the social stigma the word carries.

Children who are classified in the top 15th percentile are at risk of developing weight-related health problems. However, one criticism of BMI is that it does not take into consideration factors like muscle mass. Certain adolescent athletes, such as wrestlers or weightlifters, may be categorized as overweight or obese when using BMI calculations, even if they are fit and in good health.

Demographics

There is no doubt that American children are getting heavier. In 2008, the CDC estimated that one-third of American children and adolescents were overweight or obese. Other surveys have found the total obesity rate among American children and adolescents to be between 21% and 24%. Although the problem of excessive weight is growing fastest in the United States, the trend toward heavier children is occurring in most developed countries.

In the United States, the National Center for Health Statistics has tracked children's weight for several decades and recorded the following changes in the percentage of children who are obese:

- Children ages 2–5: 1976 5.0%, 2008 10.4%
- Children ages 6–11: 1976 6.5%, 2008 19.6%
- Children ages 12–19: 1976 5.0%, 2008 18.1%

The number of children who are overweight or obese differs significantly among different races and ethnic groups. Significantly more Hispanic-American boys are obese than non-Hispanic black or white boys.

Significantly more Hispanic American girls and non-Hispanic black girls are obese than white girls. Native American and Native Hawaiian children also have higher rates of obesity than whites.

Causes and symptoms

At its simplest, obesity is caused by taking in more calories than the body uses. This difference is called the "energy gap." A 2006 study carried out a the Harvard School of Public Health and published in the journal *Pediatrics* found that, on average, American children consumed between 110 and 165 more calories every day than they expended. Over a 10-year period, these extra calories add 10 lb (4.5 kg) to their weight. However, already overweight teens took in an average of 700–1,000 extra calories every day, resulting in an average of 58 extra lb (26 extra kg).

Causes

There are many reasons why the energy gap exists. These reasons are related to both increased food intake and decreased energy use. Food intake reasons include:

- increased consumption of sugar-containing beverages and decreased consumption of low fat milk and water
- tendency to supersize portions; in some fast food restaurants portions have almost tripled since the 1970s
- more meals eaten away from home
- more use of prepared foods in the home
- increased snacking between meals along with fewer meals eaten together as a family
- heavy advertising of high-sugar, high-fat foods to children
- decrease in children carrying their lunch to school from home
- poor eating habits such as skipping breakfast and later snacking on high-fat, sugary foods

Inadequate energy use reasons include:

- more time spent watching television, playing video games, or using the computer than playing outside
- fewer physical education requirements at school—many schools do not require or provide a regularly scheduled recess
- fewer children walking to school—in 1969, half of all schoolchildren walked or biked to school, but by 2003 (the date of the most recent CDC study), the rate had dropped to 15%
- fear of crime, which limits outdoor activities of children and walking to school
- more affluence—teen access to cars has increased over the past 30 years

According to a 2012 study published in the *Journal of Teaching in Physical Education*, only six states required at least 150 minutes of physical activity in elementary schools and only two states required 225 minutes in middle schools, the amounts recommended by the National Association of Sport and Physical Education. No states met the guidelines for high schools, which were also 225 minutes of activity per week. The U.S. Centers for Disease Control and Prevention recommends that children ages six to 17 participate in at least one hour of physical activity each day.

Other factors that affect childhood obesity include an inherited tendency toward weight gain; mental illness; **binge eating disorder**; eating in response to **stress**, boredom, or loneliness; poor sleeping habits; and having at least one obese parent.

In rare cases, medical or genetic disorders can cause obesity. For example, **Prader-Willi syndrome** is a genetic disorder that causes an uncontrollable urge to eat. The only way to prevent a person with Prader-Willi disorder from constant eating is to keep them in an environment where they have no free access to food. Other genetic and hormonal disorders (e.g., **hypothyroidism**) can cause obesity. Certain medications also can cause weight gain (e.g., cortisone, tricyclic antidepressants), but these situations are the exception. Researchers estimate that fewer than 10% of cases of childhood obesity are associated with hormonal or genetic causes. Most children are too heavy because they eat too much and/or **exercise** too little.

Symptoms

The most obvious symptom of obesity is an accumulation of body fat. Other symptoms involve changes in body chemistry. Some of these changes cause disease in children, while others put the child at risk for developing health problems later in life. Children who are obese are at increased risk of:

- type 2 diabetes; this disease is appearing in adolescents and young adults at an alarmingly high rate, whereas in the past, it was usually seen in older adults
- high blood pressure (hypertension)
- fat accumulation in the liver (fatty liver/liver disease)
- sleep apnea
- early puberty; early start of menstruation in girls
- eating disorders

WWW.BOOKBAZ.IR

- joint pain
- depression
- increased anxiety and stress
- low self-worth
- exposure to social prejudice and discrimination

Diagnosis

Diagnosis of obesity is usually made based on the child's BMI. To better assess the problem, the physician will take a family history and a medical history and do a complete **physical examination**, including standard blood and urine tests. A thyroid hormone test may be done to rule out hypothyroidism as the cause of obesity. Based on the physician's findings, other tests may be performed to rule out medical causes of obesity.

Treatment

Obese children and their parents may be referred to a registered dietitian or nutritionist who can help them develop a plan to replace high-fat/energy foods with nutrient-rich, low-calorie foods. **Nutrition** education usually involves the entire family. Children may be asked to keep a food diary to record everything that they eat in order to determine what changes in behavior and diet need to be made. Typically, children are encouraged to increase their level of physical activity rather than to drastically reduce calorie intake.

Drug therapy and weight-loss surgery are very rarely used in children, except in the most extreme cases of health-threatening obesity when other methods of weight control have failed. Some teenagers may benefit from joining a structured weight-loss program such as Weight Watchers or Jenny Craig. They should check with their physician before joining.

Teaching children how to eat a healthy diet sets a framework for their lifetime eating habits. A nutritionist or dietitian can help families to understand how much and what kinds of food are appropriate for their child's age, weight, and activity level.

The American Heart Association has adapted the following dietary suggestions for children over two (unless otherwise specified). Separate guidelines exist for infant nutrition.

- For children over three, limit fat intake to 25–30% of total calories. Fat sources should be low in saturated and *trans* fats.
- Consume a variety of colorful fruits and vegetables daily, but limit fruit juice due to its sugar content.
- Select high-fiber, whole-grain cereals and breads.
- Limit sugary drinks and foods, such as carbonated soft drinks, candy, and baked goods.
- Drink fat-free or low-fat milk after age two. Children younger than two have higher energy requirements and need the benefits of dietary fat, including improved absorption of fat-soluble vitamins, for proper growth and development of the nervous system. Other good sources of calcium include low-fat or fat-free yogurt and cottage cheese.
- Eat a variety of foods, including fish and shellfish; oily fish such as salmon provide healthy fats.
- Do not add extra salt to foods and reduce overall sodium intake.
- Balance calories consumed with regular physical activity to help maintain a healthy weight.

It is often difficult for parents to understand how much food their child should eat at a particular age. Parents tend to overestimate the amount of food small children need. The daily amounts of some common foods that meet the American Heart Association guidelines for different ages are based on children who are sedentary or physically inactive. Active children will need more calories and slightly larger amounts of food. Calorie and serving recommendations are as follows:

- children ages two to three: total daily calories, 1,000; milk, 2 cups; lean meat or beans, 2 ounces; fruits, 1 cup; vegetables, 1 cup; grains, 3 ounces
- girls ages four to eight: total daily calories, 1,200; milk, 2 cups; lean meat or beans, 3 ounces; fruits, 1.5 cups; vegetables, 1 cup; grains, 4 ounces
- boys ages four to eight: total daily calories, 1,400; milk, 2 cups; lean meat or beans, 4 ounces; fruits, 1.5 cup; vegetables, 1.5 cups; grains, 5 ounces
- girls ages nine to 13: total daily calories, 1,600; milk, 3 cups; lean meat or beans, 5 ounces; fruits, 1.5 cups; vegetables, 2 cups; grains, 5 ounces
- boys ages nine to 13: total daily calories, 1,800; milk, 3 cups; lean meat or beans, 5 ounces; fruits, 1.5 cups; vegetables, 2.5 cups; grains, 6 ounces
- girls ages 14 to 18: total daily calories, 1,800; milk, 3 cups; lean meat or beans, 5 ounces; fruits, 1.5 cups; vegetables, 2.5 cups; grains, 6 ounces
- boys ages 14 to 18 years: total daily calories, 2,200; milk, 3 cups; lean meat or beans, 6 ounces; fruits, 2 cups; vegetables, 3 cups; grains, 7 ounces

Treatment

Children who are overweight or obese may have accompanying psychological and social problems that may be helped with **psychotherapy** in addition to

KEY TERMS

Body mass index (BMI)—Also known as BMI, the index determines whether a person is at a healthy weight, underweight, overweight, or obese. The BMI can be calculated by converting the person's height into inches. That amount is multiplied by itself and then divided by the person's weight. That number is then multiplied by 703. The metric formula for the BMI is the weight in kilograms divided by the square of height in meters.

Cognitive behavioral therapy—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

nutritional counseling. **Cognitive-behavioral therapy** (CBT) is designed to confront and change thoughts and feelings about one's body and behaviors toward food. CBT is relatively short-term and does not address the origins of those thoughts or feelings. CBT may include strategies to maintain self-control with regard to food. **Family therapy** may help children who overeat for emotional reasons related to conflicts within the family. Family therapy teaches strategies for reducing conflict, disorder, and stress that may be factors in triggering emotional eating.

Prognosis

The younger the child is when weight control strategies begin, the better the chance that the child will be able to maintain a normal weight. When it comes to weight control, one advantage children have over adults is that they grow. If a child can maintain his weight without gaining, he may grow into a normal weight as he becomes taller.

Parents need to be careful about how they approach weight loss in children. Critical comments about weight from parents or excess zeal in putting their child on a rigorous diet can trigger **eating disorders** such as **anorexia nervosa** or **bulimia nervosa** in some children, especially adolescent girls. Instead of placing their child on a diet, parents should promote healthy eating and prepare meals that include lots of fruits and vegetables, whole grains, and low-fat dairy and lean protein. It is helpful for parents to lead by example, so that the child does not feel isolated. Criticism and focus on losing weight as opposed to getting healthy may lead to a negative **body image**.

Children who remain overweight or obese have a much greater likelihood of being overweight or obese adults with all the health problems that obesity brings. Studies have found that 26–41% of preschoolers who are obese become obese adults. In school-aged children, 42–63% of children with obesity become obese adults. The relationship between obesity in early life and adulthood is strongest for adolescents, so it is important to deal with childhood obesity as soon as possible.

Prevention

Parents must take the lead in preventing obesity in children. Starting good eating habits in children when they are young may help them carry such practices into adult life. Some of the ways parents can promote healthy habits are:

- serve a healthy variety of foods; keep healthy snacks on hand
- choose low-fat cooking methods such as broiling or baking
- eliminate high-fat and high-calorie snack food and sugary beverages from the house; this removes temptation and eliminates the need to nag
- eat meals together as a family rather than grabbing something quick on the run
- limit visits to fast-food restaurants
- limit television, computer, and video game time
- plan family activities that involve physical activity, such as hiking, biking, or swimming
- encourage children to become more active in small ways such as walking to school, biking to friends' houses, or doing chores such as walking the dog or mowing the lawn
- avoid using food as a reward
- pack healthy homemade lunches on school days
- encourage school officials to eliminate soda machines on campus, bake sales, and fundraising with candy and cookies
- set realistic goals for weight control and reward children's efforts (but not with food)
- model the eating behaviors and active lifestyle you would like your child to adopt

REVISED BY TISH DAVIDSON, AM

Children's health

Definition

Children's health encompasses the physical, mental, emotional, and social well-being of children from infancy through adolescence.

Common childhood infections

Infection	Symptom(s)
Common cold	Runny nose, sneezing, cough, congestion
Conjunctivitis (pink eye)	Redness of the eye, pus-like discharge
Head lice	Intense itching, possible swelling of neck glands
Influenza	Fever, cough, chills, headache, fatigue, general discomfort
Mononucleosis	Weakness, fatigue, sore throat, fever, swollen lymph nodes
Otitis media (middle ear infection)	Fever, ear pulling, complaints of ear pain or fullness
Strep throat	Sore throat, fever, fatigue, swollen tonsils
Varicella (chickenpox)	Itchy, red, blistery rash; fever

(Table by PreMediaGlobal. © Cengage Learning®.)

Description

In today's society, children are affected by certain health and lifestyle issues that were not as prevalent when their parents were young, such as **childhood obesity**, type 2 diabetes, **suicide**, and substance abuse. According to the Centers for Disease Control and Prevention (CDC), suicide is the third leading cause of death between the ages of 10 and 24 years. These health and lifestyle issues are reflected in pediatric assessment standards, which were updated in 2014 as follows:

- Information regarding a screening tool was added to the alcohol and drug assessment.
- A depression screening was added for ages 11 through 21 years.
- An additional screening for lipids in the blood has been added to the check up for children ages nine to 11 years.
- A risk assessment for anemia has been added for children ages 15 months to 30 months.
- An HIV screening has been added for adolescents ages 16 to 18 years.
- The age for first screening of cervical disorders is now 21 years.
- Newborns are screened for congenital heart disease after the first 24 hours of life and before discharge from the birthing center.

All children should have regular well-child check-ups according to the schedule recommended by their physician or pediatrician. The American Academy of Pediatrics (AAP) advises that children be seen for well-baby checks at two weeks, two months, four months, six months, nine months, 12 months, 15 months, and 18 months. In 2014, the AAP updated its schedule of recommended well child check ups. For the baby's first year, the recommended schedule includes a prenatal visit and then at birth, three to five days, one month, two months, four months, six months, nine months, and one year. During the second year of life, the recommendation includes assessments at 15 months, 18 months, and 24 months, followed by an assessment at 30 months. Beginning at age three, the recommendation is for assessments once a year through age 21.

Well-baby and well-child check-ups assess the child physically, behaviorally, developmentally, and emotionally and are important in spotting developmental delays or behavioral abnormalities early. Well-child check-ups usually include reviewing medical history; measuring height, weight, blood pressure, and temperature; vision, hearing, and reflex screening; a developmental/behavioral assessment; **physical examination**; immunizations; guidance about developmental milestones, **nutrition**, and injury prevention; and referrals as needed to a pediatric dentist or other pediatric specialists. A study published in 2010 found that 40% of teenagers only had a wellness exam once between the ages of 13 and 17 years. A 2012 study noted that 75% of children had contact with a health care professional within a given six month period.

Immunization to protect against specific diseases is an important part of a child's healthcare program. Vaccines must be administered within certain time limits. When multiple doses are needed, a certain amount of time must elapse between each dose. As of 2014, the AAP and CDC recommended these childhood immunizations for healthy children (children in certain high-risk groups for a particular illness may receive additional vaccinations at the recommendation of their health care provider):

- Hepatitis B vaccine. Three doses, beginning at birth, before the baby leaves the birthing center. The second dose is given between one and two months, and the third dose between six months and eighteen months of age.
- Rotavirus vaccine. Two or three doses depending on vaccine with the first dose given at two months and the second dose at four months. If the three dose series is used, the third dose is given at six months.

WWW.BOOKBAZ.IR

- Diphtheria, tetanus, and pertussis (DTaP) vaccine. The child receives this vaccine by injection five times: ages two months, four months, six months, between 15 months and 18 months, and between four years and six years. After age seven years, the DTaP is not administered. For children age seven years through adulthood, two vaccines are available: Tdap and Td, which are boosters because the immunity to diphtheria, tetanus, and pertussis diminishes over time. A booster is given at 11 to 12 years of age. If children are behind schedule in receiving this vaccine, the health care provider may recommend doses between nine months and 15 months and between 19 months and four years of age.
- *Haemophilus influenzae* type b (Hib) vaccine. Two doses are given, first at two months and then at four months. Children with health issues, such as weakened immune systems, may receive a third or fourth dose. The health care provider will recommend the scheduled intervals for the additional doses.
- Pneumococcal conjugate vaccine (PCV13). Doses at two, four, six, and 12 to 15 months. High-risk children may require additional doses of related vaccine. Catch-up doses may be given at nine months and between 18 months and about five years.
- Inactivated polio vaccine. Doses are given at two, four, and six to 18 months and four to six years.
- Influenza vaccine. Annual vaccines beginning at ages six months are recommended. The inactivated form of the vaccine is recommended for ages six months to two years. After age two, a healthy child may qualify to receive the live attenuated vaccine, or may receive the inactivated form of vaccine. In the 2013–2014 flu season, two annual doses were recommended for children ages two months through eight years who received their first-ever dose of influenza vaccine.
- Measles, mumps, rubella (MMR) vaccine. Two doses are recommended, with the first between 12 and 15 months of age and the second between ages four and six years.
- Varicella (chickenpox) vaccine. Two doses are recommended, with the first between 12 months and 18 months and the second between four to six years.
- Hepatitis A (HepA) vaccine. Two doses are recommended, given between 12 months and 23 months. The two doses are given six to 18 months apart.
- Meningococcal vaccine. One dose is recommended between the ages of 11 and 12 years with a booster at 16 years of age.
- Human papillomavirus (HPV) vaccine. This vaccine is given to girls and boys, in a three-dose series between ages 11 to 12 years.

In 2012, more than 48,000 Americans suffered from whooping **cough** (pertussis), which was the most cases in the preceding 50 years. It is believed that the increasing number of cases is due to several factors: the newer vaccines do not provide immunity for as long as they did in the past; some parents do not vaccinate their children; and even people who were vaccinated can be carriers of the disease. Due to the resurgence of this disease, the CDC recommends that pregnant women discuss with their physician the need to obtain a Tdap (tetanus/diphtheria/pertussis) vaccine. The CDC recommendation is for pregnant women to receive the Tdap vaccine during each **pregnancy**, between weeks 27 and 36 of gestation. By doing so, the woman's body will create antibodies to help protect the baby against whooping cough in the early part of his or her life. It is also important for anyone that has contact with the baby to have a whooping cough vaccine.

In its early stage, whooping cough is similar to a cold; however, after a week or so the dangerous coughing begins. Sometimes the cough is constant, and there is no air left in the lungs, causing the person to make the whooping noise as he or she tries to inhale. Babies may not have this cough; instead, they may have periods of apnea (not breathing), which may threaten their lives.

Mental health

Children who have difficulty in areas of language acquisition, cognitive (mental) development, and behavior control may have a mental health disorder. Mental health problems that arise in children include:

- Attention deficit hyperactivity disorder (ADHD). ADHD is estimated to affect 3 to 7% of school-age children in the United States and is three to five times more common in boys than in girls. It is a disorder characterized by excessive motor activity, distractibility, and poor impulse control.
- Learning disorders. Learning disabilities affect one in 10 school children in the United States.
- Depression, anxiety, and bipolar disorder. Affective, or mood, disorders are now more commonly recognized in children than in the past.
- Eating disorders. Anorexia nervosa, bulimia nervosa, and binge eating disorder frequently occur in adolescent girls. It is estimated that one out of every 100–200 adolescent girls meets all the diagnostic criteria for anorexia.

- Schizophrenia. A disorder characterized by bizarre thoughts and behaviors, paranoia, impaired sense of reality, and psychosis may be diagnosed in childhood or adolescence.
- Obsessive-compulsive disorder (OCD). Symptoms often begin in childhood or adolescence.
- Autism and pervasive developmental disorder. Severe developmental disabilities that cause a child to become withdrawn and unresponsive.
- Intellectual disabilities (ID). Children under age 18 with an IQ of 70 or below and impairments in adaptive functioning are considered intellectually disabled.

Emotional and social health

Children take their first significant steps toward socialization and peer interaction when they begin to engage in cooperative play at around age four. Their social development progresses throughout childhood and adolescence as they expand their social contacts, develop friendships, start to be influenced by their peers, and begin to show interest in the opposite sex. In adolescence, there is a strong, but normal, trend away from involvement with family and toward establishing their own identity and values.

Several factors may have a negative impact on the emotional and social well-being of children:

- Violence. Bullying can cause serious damage to a child's sense of self-esteem and personal safety, as can experiences with community violence.
- Family turmoil. Divorce, domestic abuse, death of a family member, and other life-changing events that alter the family dynamic can have a serious impact on a child. Even a positive event such as the birth of a sibling or a move to a new city and school can put emotional strain on a child.
- Stress. The pressure to perform well academically and in extracurricular activities such as sports can be overwhelming to some children. Emphasis on physical appearance also creates stress that can lead to eating disorders.
- Peer pressure. Although it can have a positive impact, peer pressure is often a source of significant stress for children. This is particularly true in adolescence when "fitting in" is important to most teens.
- Drugs and alcohol. Curiosity is intrinsic to childhood, and more than 30% of children have experimented with alcohol by age 13. Open communication with children that sets forth parental expectations about drug and alcohol use is essential.
- Negative sexual experiences. Sexual abuse and assault can emotionally scar a child and instill negative feelings about sexuality and relationships. Early and/or indiscriminate sexual relationships can cause emotional harm and increase the likelihood of pregnancy and sexually transmitted diseases.

Causes and symptoms

Childhood health problems may be congenital (i.e., present at birth) or acquired through infection, immune system deficiency, or another disease process. They may also be caused by physical **trauma** (e.g., a car accident or a playground fall), exposure to a toxic substance (e.g., drug allergy, or exposure to poisonous chemical), or triggered by a genetic factor (e.g., **celiac disease**, sickle cell anemia) or environmental factors (e.g., dust mite **allergies**, pollen allergies).

Childhood **obesity** may lead to a plethora of health issues. A study released in 2014 revealed that nearly one-third of children ages two years to 18 years had abdominal obesity when waist-to-height ratio was used as the criteria. Waist-to-height ratio of $^{3}0.5$ defines obesity according to this method. The positive news from this study was that the incidence of abdominal obesity had remained steady (did not increase) between 2003–2004 and 2011–2012.

Physical and mental health problems in childhood can cause a wide spectrum of symptoms. The following behaviors suggest a larger emotional, social, or mental disturbance that may need to be evaluated by a health care professional.

- signs of alcohol and drug use
- suddenly falling grades or school avoidance
- lack of interest in activities that were previously enjoyable
- excessive anxiety
- persistent, prolonged depression
- withdrawal from friends and family
- involvement with violence or vandalism
- extreme or irrational perfectionism
- repeated, aggressive confrontations with authority figures
- age-inappropriate temper tantrums or inappropriate displays of anger
- self-inflicted injury
- bizarre behavior and/or speech
- trouble with the police
- sexual promiscuity
- prolonged, unexplained fatigue
- suicide threats or attempts

WWW.BOOKBAZ.IR

The causes of developmental disorders and delays and learning disabilities are not always fully understood. Pervasive developmental disorder (PDD) and autistic spectrum disorder (more commonly known as **autism**) are characterized by unresponsiveness and severe impairments in one or more of these areas:

- Social interaction. Autistic children often have difficulty interpreting social cues and are unaware of acceptable social behavior. They tend to be withdrawn and socially isolated. They frequently reject physical contact.
- Communication and language. A child with autism or PDD may not speak or may display limited or immature language skills.
- Behavior. Autistic or PDD children may have difficulty dealing with anger, can be self-injurious, and may display obsessive behavior.

Autism is associated with brain abnormalities, but the exact mechanisms that trigger the disorder are yet to be determined. Research suggests that it may be linked to certain congenital conditions such as **neurofibromatosis**, **fragile X syndrome**, and **phenylketonuria** (PKU). Despite much speculation, no well-designed, controlled studies have shown any link between autism and childhood vaccinations.

Lifestyle choices

Children who spend more time in sedentary activities are at more risk for type 2 diabetes and obesity. A study released in 2013 found that children who were obese spent much more time sedentary activities than their counterparts who were not obese. The study also found a correlation between a sedentary lifestyle and the development of type 2 diabetes. The study concluded that treatment protocols for children with type 2 diabetes should include modalities to increase their physical activity.

Use of tobacco, drugs, and alcohol are also lifestyle choices that impact the lives of youth. A study released in 2013 found that restricting youth access to tobacco reduces usage. Another study, also published in 2013, found that interventions lead to lower misuse of substances.

Diagnosis

Physical, intellectual, emotional, and social maturation are all-important markers of a child's overall health and well being. When evaluating children, pediatricians and child-care specialists assess related skill sets, such as a child's acquisition and use of language, fine and gross motor skills, cognitive growth, socialization, and achievement of certain milestones in these areas. A developmental milestone is a task or skill set that a child is expected to reach at a certain age or stage of life. For example, by age one, most children have achieved the physical milestone of walking with the assistance of an adult. Developmental disorders may be identified and/or diagnosed by physicians, teachers, child psychologists, therapists, counselors, and other professionals who interact with children on a regular basis.

It is important to remember that all children are unique, and develop at different paces within this broad framework. Reaching a milestone early or late does not necessarily indicate a developmental problem. However, if a child is consistently lagging in achieving milestones or has a significant deficit in one developmental area, he or she may be experiencing developmental delays that warrant professional evaluation.

Pediatricians and other medical professionals typically diagnose physical illness and disease in children as well as provide preventative health care. In cases of illness and injury, children will undergo a thorough physical examination and patient history. Diagnostic tests may be performed as appropriate. In cases of mental or emotional disorders, a psychologist or psychiatrist will meet with the patient to conduct an interview and take a detailed social and medical history. Interviews with a parent or guardian and teacher may also be part of the diagnostic process. The physician may also administer one or more **psychological tests** (also called clinical inventories, scales, or assessments).

Treatment

Medications may be prescribed to treat certain childhood illnesses. Proper dosage is particularly important with infants and children, as medications such as **acetaminophen** can be toxic in excessive amounts. Parents and caregivers should always follow the instructions for use that accompany medications, and inform the child's pediatrician if the child is taking any other drugs or **vitamins** to prevent potentially negative **drug interactions**. Any side effects or adverse reactions to medication should be reported to the child's physician. If **antibiotics** are prescribed, the full course should always be taken. Parents should be especially careful when using herbal medicine or dietary supplements, as the pediatric doses for these treatments often have not been established.

Other treatments for childhood illness and/or injuries include, but are not limited to, nutritional therapy, **physical therapy**, **respiratory therapy**, medical devices (e.g., **hearing aids**, glasses, braces), and, in some cases, surgery.

KEY TERMS

Bipolar disorder—Formerly called manic-depressive disorder. A mood disorder characterized by alternating periods of overconfidence and activity (manic highs) and depressive lows.

Child development—The process of physical, intellectual, emotional, and social growth that occurs from infancy through adolescence. Erik Erikson, Margaret Mahler, Sigmund Freud, and Jean Piaget are among the most well-known child development theorists.

Immunization—Administering a vaccine that stimulates the body to create antibodies to a specific disease (immunity) without causing symptoms of the disease.

Learning disabilities—An impairment of the cognitive processes of understanding and using spoken and written language that results in difficulties with one or more academic skill sets (e.g., reading, writing, mathematics).

Motor skills—Controlled movement of muscle groups. Fine motor skills involve tasks that require dexterity of small muscles, such as buttoning a shirt. Tasks such as walking or throwing a ball involve the use of gross motor skills.

Obsessive-compulsive disorder (OCD)—An anxiety disorder in which a person cannot prevent himself from dwelling on unwanted thoughts, acting on urges, or performing repetitious rituals, such as washing his hands or checking to make sure he turned off the lights.

Psychological tests—Written, verbal, or visual tasks that assess psychological functioning, intelligence, and/or personality traits.

Type 1 diabetes—A chronic immune system disorder in which the pancreas does not produce sufficient amounts of insulin, a hormone that enables cells to use glucose for energy. Also called juvenile diabetes, it must be treated with insulin injections.

Counseling is typically a first treatment for psychological disorders. Therapy approaches include **psychotherapy**, cognitive therapy, behavioral therapy, family counseling, and **group therapy**. Therapy or counseling may be administered by social workers, nurses, licensed counselors and therapists, psychologists, or psychiatrists. Psychoactive medication may be prescribed by a psychiatrist for symptom relief in children and adolescents with mental disorders.

Support groups may provide emotional support for children with chronic illnesses or mental disorders. This approach, which allows individuals to seek advice and counsel from others in similar circumstances, can be extremely effective, especially in older children who look toward their peers for guidance and support. Support groups for family members often help adults and siblings cope with a chronically ill child.

Speech therapy may help children with developmental delays in language acquisition. Children with **learning disorders** can benefit from special education classes and accommodations arrived at through professional evaluation and the creation of an individualized educational plan (IEP).

Alternatives

Therapeutic approaches that encourage self-discovery and empowerment may be useful in treating some childhood emotional traumas and mental disorders. **Art therapy**, the use of the creative process to express and understand emotion, encompasses a broad range of humanistic disciplines, including visual arts, dance, drama, music, film, writing, literature, and other artistic genres. It can be particularly effective in children who may have difficulty gaining insight to emotions and thoughts they are otherwise incapable of expressing.

Certain mild herbal remedies may also be safely used with children, such as ginger (*Zingiber officinale*) tea for nausea and aloe vera salve for **burns**. Parents and caregivers should always consult their healthcare provider before administering herbs to children, as certain herbs may affect children differently than adults.

Prognosis

The prognosis for childhood health problems varies widely. In general, early detection and proper treatment can greatly improve the odds of recovery from many childhood illnesses and disabilities. Early intervention is key in helping a child with disabilities reach his or her full potential.

Some learning disabilities and mild developmental disorders can be overcome or greatly improved through appropriate therapies. There is no known medical treatment or pharmacological therapy that eliminate all of the symptoms associated with pervasive developmental disorder (PDD), autism spectrum disorder, and ID. Mental illnesses such as **schizophrenia** and **bipolar disorder** are chronic, lifelong disorders, although their symptoms can often be controlled with medication.

WWW.BOOKBAZ.IR

DR. BENJAMIN SPOCK (1903–1998)

(The Library of Congress.)

Benjamin Spock, pediatrician and political activist, was most noted for his authorship of *Baby and Child Care*, which significantly changed predominant attitudes toward the raising of infants and children. He began medical school at Yale University in 1925, and transferred to Columbia University's College of Physicians and Surgeons in 1927. Spock had decided well before starting his medical studies that he would "work with children, who have their whole lives ahead of them" and so, upon taking his M.D. degree in 1929 and serving his general internship at the prestigious Presbyterian Hospital, he specialized in pediatrics at a small hospital crowded with children in New York's Hell's Kitchen area.

On a summer vacation in 1943, he began to write his most famous book and he continued to work on it from 1944 to 1946 while serving as a medical officer in the Navy. The book sharply broke with the authoritarian tone and rigorous instructions found in earlier generations of baby-care books, most of which said to feed infants on a strict schedule and not to pick them up when they cried. Spock, who spent 10 years trying to reconcile his psychoanalytic training with what mothers were telling him about their children, told his readers, "You know more than you think you do.... Don't be afraid to trust your own common sense.... Take it easy, trust your own instincts, and follow the directions that your doctor gives you." The response was overwhelming. *Baby and Child Care* rapidly became America's all-time best-seller except for Shakespeare and the Bible; by 1976 it had also eclipsed Shakespeare.

Spock prided himself in keeping up with the times, a fact that's reflected in the many revisions of *Baby and Child Care* in which he incorporated the latest medical developments and dealt with emerging social issues such as working mothers, daycare centers, and single parenthood.

Prevention

Parents can take precautions to ensure the safety of their children. Childproofing the home, following a recommended immunization schedule, educating children on safety, learning **first aid**, and taking children for regular well-child check-ups can help to protect against physical harm. In addition, encouraging open communication with children can help them grow both emotionally and socially. Providing a loving and supportive home environment can help to nurture an emotionally healthy child who is independent, self-confident, socially skilled, insightful, and empathetic toward others.

Because they are still developing motor skills, children may be particularly accident prone. Observing the following safety guidelines may help protect children from injury:

- Helmets and padding. Children should always wear a properly fitted helmet and appropriate protective gear when riding a bike, scooter, or similar equipment or participating in sports. They should ride on designated bike paths whenever possible, and learn bicycle safety rules (i.e., ride with traffic, use hand signals).
- Playground safety. Swing sets and other outdoor play equipment should be well-maintained, have at least 12 in (30 cm) of loose fill materials (e.g., sand, wood chips) underneath to cushion falls, and children should be properly supervised at play.
- Staying apprised of recalls. Children's toys, play equipment, and care products are frequently involved in product recalls. The U.S. Consumer Safety Products Commission (CSPC) is the agency responsible for tracking these recalls.
- Staying safe in the car. Up to 85% of children's car seats are improperly installed and/or used. Infants should always be in a rear-facing car seat until they are over 12 months of age and weigh more than 20 lb (9 kg). An infant or car seat should never be put in a front passenger seat that has an air bag. Once they

outgrow their forward facing car seats, children between the ages of four and eight who weigh between 40–80 lb (18–36 kg) should ride in a booster seat. Every child who rides in a car over this age and weight should use a properly fitted lap and shoulder belt.

- Teaching children pedestrian safety. Young children should never be allowed to cross the street by themselves. Older children should know to follow traffic signs and signals, cross the street at the corner, and look both ways before stepping off the curb.
- Teaching children about personal safety. Children should know what to do in case they get lost or are approached by a stranger. It is also imperative that parents talk openly with their children about their body and sexuality, and what behavior is inappropriate, to protect them against sexual predators.
- Teaching children Internet safety. Children may access the Internet at home, school or in a library. They should be taught not to ever provide their name, address, name of their school, or any other personal information over the Internet and to never arrange to meet in person with someone they only know from the Internet. They should report to their parents anything they find that does not seem right. They should also be instructed that sometimes people are not who or what they say they are (they may be posing as someone else).
- Teaching children about safety from bullying. Bullying is aggressive behavior in which the bully demonstrates aggressiveness over the child being bullied. Any child is at risk for bullying but there may be increased risk for young persons who are lesbian, gay, bisexual, or transgendered (LGBT), disabled or socially isolated. Other risk factors are children who others perceive as "different" (wear glasses or are overweight, for example), as well as children who may be depressed, not as popular as their peers or who have difficulties getting along with others. Children should be encouraged to speak to an adult that they trust if they are the victims of bullying or if they see others getting bullied. Adults should talk to children about how to stay safe, such as remaining with adults if bullies are around or staying with a group of their peers to avoid being alone.

Childproofing the household is an important step toward keeping children healthy. To make a house a safe home, parents and caregivers should:

- Guns should be kept away from children. Accidental shootings in the home injure an estimated 1,500 children under age 14 each year. If a gun must be in the home, it should be securely locked in a tamper proof gun safe with the ammunition kept locked in a separate place.
- Matches, lighters, and flammable materials should be properly stored and out of the reach of children.
- Hot water heaters should be set to 120°F (49°C) or below to prevent scalding injuries.
- The home should be equipped with working fire extinguishers and smoke alarms; children should be taught what to do in case of fire.
- All medications (including vitamins, herbs, and supplements), as well as hazardous chemicals and poisonous substances (including alcohol and tobacco), should be secured in ways that they cannot be accessed by children.
- Smoking should not take place in a child's home as second-hand smoke is hazardous to a child's health (e.g., increases their risk of developing allergies).
- Small children should be kept away from poisonous plants outdoors; toxic indoor plants should be removed from the home.
- The home should included posted numbers of poison control and the pediatrician near the phone; children should be taught how to dial 9-1-1 and report an emergency.
- Children under age five should never be left alone in the bathtub, wading pool, or near any standing water source (including an open toilet). All swimming pools should be fenced and be secured with a self-latching gate. Drowning is the leading cause of death by injury for children between the ages of one and four in the United States.
- Lead paint should be removed. Lead is a serious health hazard for children and can cause cognitive retardation. Houses built before 1978 should be tested for lead paint. If lead is found, the paint should be removed using the appropriate safety precautions.
- Adults should be alert to coins, small play pieces, and similar items that are choking hazards for small children.

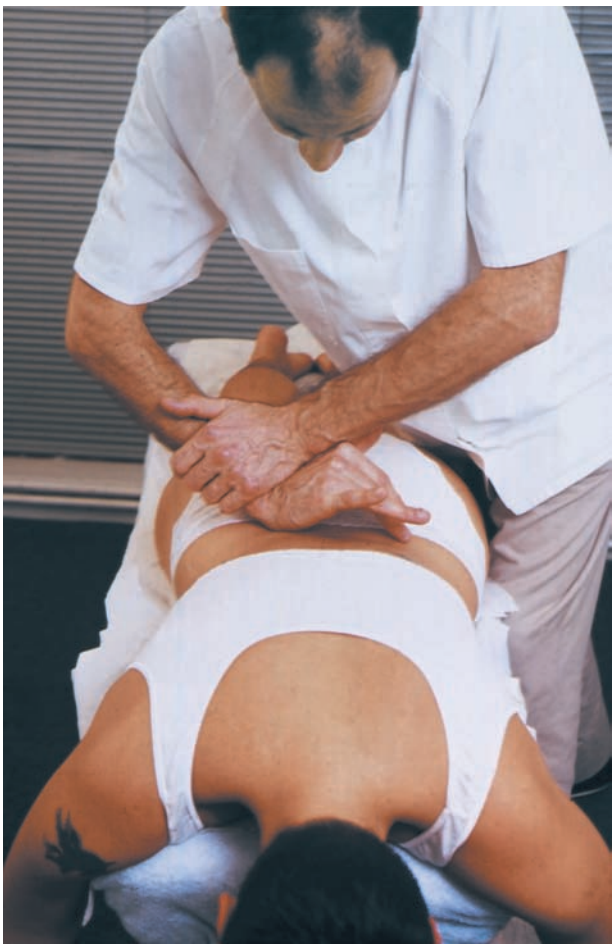
Chiropractic

Definition

Chiropractic is from Greek words meaning done by hand. It is grounded in the principle that the body can heal itself when the skeletal system is correctly aligned and the nervous system is functioning properly. To achieve this, the practitioner uses his or her hands or an adjusting tool to perform specific manipulations of the vertebrae. When these bones of the spine are not correctly articulated, resulting in a condition known as subluxation, the theory is that nerve transmission is disrupted and causes **pain** in the back, as well as other areas of the body.

Chiropractic is one of the most popular alternative therapies currently available. Some would say it now qualifies as mainstream treatment as opposed to complementary medicine. Chiropractic treatment is covered by many insurance plans and in 2004, the U.S. Department of Veterans Affairs announced full inclusion of chiropractic care for veterans. It has become well-accepted treatment for acute pain and problems of the spine, including lower back pain and **whiplash**. Applications beyond that scope are not supported by current evidence, although there are ongoing studies into the usefulness of chiropractic for such problems as ear



An example of a McTimoney chiropractic technique on patient's lumbar vertebra. The McTimoney chiropractic is a system of adjustment by hand of displacements of the spinal column and bones. It can also be applied to animals. *(Custom Medical Stock Photo, Inc.)*

infections, **dysmenorrhea**, infant **colic**, migraine headaches, and other conditions.

Purpose

Most people will experience back pain at some time in their lives. Injuries due to overexertion and poor posture are among the most common. Depending on the cause and severity of the condition, options for treatment may include **physical therapy**, rest, medications, surgery, or chiropractic care. Chiropractic treatment carries none of the risks of surgical or pharmacologic treatment. Practitioners use a holistic approach to health. The goal is not merely to relieve the present ailment, but to analyze the cause and recommend appropriate changes of lifestyle to prevent the problem from occurring again. They believe in a risk/benefit analysis before use of any intervention. The odds of an adverse outcome are extremely low. Chiropractic has proven in several studies to be less expensive than many more traditional routes such as outpatient physical therapy. Relief from some neuromuscular problems is immediate, although a series of treatments is likely to be required to maintain the improvement. Spinal manipulation is an excellent option for acute lower back pain, and may also relieve neck pain as well as other musculoskeletal pain. Although most back pain will subside eventually with no treatment at all, chiropractic treatment can significantly shorten the time it takes to get relief. Some types of **headache** can also be successfully treated by chiropractic.

Description

Origins

Spinal manipulation has a long history in many cultures but Daniel D. Palmer is the founder of modern chiropractic theory, dating back to the 1890s. A grocer and magnetic healer, he applied his knowledge of the nervous system and manual therapies in an unusual situation. One renowned story concerns Harvey Lillard, a janitor in the office where Palmer worked. The man had been deaf for 17 years, ever since he had sustained an injury to his upper spine. Palmer performed an adjustment on a painful vertebra in the region of the injury and Lillard's hearing was reputedly restored. Palmer theorized that all communication from the brain to the rest of the body passes through the spinal canal, and areas that are poorly aligned or under **stress** can cause physical symptoms both in the spine and in other areas of the body. Thus the body has the innate intelligence to heal itself when unencumbered by spinal irregularities causing nerve interference. After his success with Lillard, other patients began coming to him for care, and responded well to adjustments. This resulted in Palmer's further study of the relationship between an optimally functional spine and normal health.

Palmer founded the first chiropractic college in 1897. His son, B. J. Palmer, continued to develop chiropractic philosophy and practice after his father's death. B. J. and other faculty members were divided over the role of subluxation in disease. B. J. saw it as the cause of all disease. The others disagreed and sought a more rational way of thinking, thus broadening the base of chiropractic education. From 1910 to 1920, many other chiropractic colleges were established. Other innovators, including John Howard, Carl Cleveland, Earl Homewood, Joseph Janse,

WWW.BOOKBAZ.IR

Herbert Lee, and Claude Watkins, also helped to advance the profession.

The theories of the Palmers receive somewhat broader interpretation today. Many chiropractors believe that back pain can be relieved and health restored through chiropractic treatment even in patients who do not have demonstrable **subluxations**. Scientific development and research of chiropractic is gaining momentum. The twenty-first century will likely see the metaphysical concepts such as innate intelligence give way to more scientific proofs and reform.

Many people besides the Palmers have contributed to the development of chiropractic theory and technique. Some have gone on to create a variety of procedures and related types of therapy that have their roots in chiropractic, including McTimoney-Corley chiropractic, craniosacral manipulation, naprapathy, and **applied kinesiology**. **Osteopathy** is another related holistic discipline that utilizes spinal and musculoskeletal manipulation as a part of treatment, but osteopathic training is more similar in scope to that of an M.D.

Initial visit

An initial chiropractic exam will most often include a history and a physical. The patient should be asked about the current complaint, whether there are chronic health problems, family history of disease, dietary habits, medical care received, and any medications currently being taken. Further, the current complaint should be described in terms of how long it has been a problem, how it has progressed, and whether it is the result of an injury or occurred spontaneously. Details of how an injury occurred should be given. The physical exam should evaluate by observation and palpation whether the painful area has evidence of inflammation or poor alignment. Range of motion may also be assessed. In the spine, either hypomobility (fixation) or hypermobility may be a problem. Laboratory analysis is helpful in some cases to rule out serious infection or other health issues that may require referral for another type of treatment. Many practitioners also insist on x rays during the initial evaluation.

Manipulation

When spinal manipulation is employed, it is generally done with the hands, although some practitioners may use an adjusting tool. A classic adjustment involves a high velocity, low amplitude thrust that produces a usually painless popping noise, and improves the range of motion of the joint that was treated. The patient may lie on a specially designed, padded table that helps the practitioner to achieve the proper positions for treatment. Some adjustments involve manipulating the entire spine, or large portions of it, as a unit; others are small movements designed to affect a single joint. Stretching, **traction**, and slow manipulation are other techniques that can be employed to restore structural integrity and relieve nerve interference.

A new use of technology with traditional chiropractic care has been introduced. Using a hand-held device that is pressed to the spine or joints, a chiropractor may soon be able to detect and manipulate the skeleton not only with his or her hands but with the computer-linked device that uses harmonic frequencies to detect a misalignment in the spine. The new technology was not widely accepted in 2004, however.

Length of treatment

The number of chiropractic treatments required will vary depending on several factors. Generally longer-term treatment is needed for conditions that are chronic, severe, or occur in conjunction with another health problem. Patients who are not in overall good health may also have longer healing times. Some injuries will inherently require more treatments than others in order to get relief. Care is given in three stages. Initially appointments are more frequent with the goal of relieving immediate pain. Next, the patient moves into a rehabilitative stage to continue the healing process and help to prevent a relapse. Finally, the patient may elect periodic maintenance, or wellness treatments, along with lifestyle changes if needed to stay in good health.

Follow-up care

Discharge and follow-up therapy are important. If an injury occurred as a result of poor fitness or health, a program of **exercise** or **nutrition** should be prescribed. Home therapy may also be recommended, involving such things as anti-inflammatory medication and applications of heat or ice packs. Conscious attention to posture may help some patients avoid sustaining a similar injury in the future, and the chiropractor should be able to discern what poor postural habits require correction. A sedentary lifestyle, particularly with a lot of time spent sitting, is likely to contribute to poor posture and may predispose a person to back pain and injury.

Types of practitioners

Some practitioners use spinal manipulation to the exclusion of all other modalities, and are known

DANIEL PALMER (1845–1913)

Chiropractic inventor, Daniel David Palmer, was born on March 7, 1845, in Toronto, Ontario. He was one of five siblings, the children of a shoemaker and his wife, Thomas and Katherine Palmer. Daniel Palmer and his older brother fell victim to wanderlust and left Canada with a tiny cash reserve in April 1865. They immigrated to the United States on foot, walking for 30 days before arriving in Buffalo, New York. They traveled by boat through the St. Lawrence Seaway to Detroit, Michigan. There they survived by working odd jobs and sleeping on the dock. Daniel Palmer settled in What Cheer, Iowa, where he supported himself and his first wife as a grocer and fish peddler in the early 1880s. He later moved to Davenport, Iowa, where he raised three daughters and one son.

Palmer was a man of high curiosity. He investigated a variety of disciplines of medical science during his lifetime, many of which were in their infancy. He was intrigued by phrenology and assorted spiritual cults, and for nine years he investigated the relationship between magnetism and disease. Palmer felt that there was one thing that caused disease. He was intent upon discovering this one thing, or as he called it: the great secret.

In September 1895, Palmer purported to have cured a deaf man by placing pressure on the man's displaced vertebra. Shortly afterward Palmer claimed to cure another patient of heart trouble, again by adjusting a displaced vertebra. The double coincidence led Palmer to theorize that human disease might be the result of dislocated or luxated bones, as Palmer called them. That same year he established the Palmer School of Chiropractic where he taught a three-month course in the simple fundamentals of medicine and spinal adjustment.

Palmer, who was married six times during his life, died in California in 1913; he was destitute. His son, Bartlett Joshua Palmer, successfully commercialized the practice of chiropractic.

as straight chiropractors. Others integrate various types of therapy such as massage, nutritional intervention, or treatment with **vitamins**, herbs, or homeopathic remedies. They also embrace ideas from other health care traditions. This group is known as mixers. The vast majority of chiropractors, perhaps 85%, fall in this latter category.

Preparations

Patients should enter the chiropractic clinic with an open mind. This will help to achieve maximum results.

Risks

Chiropractic is not an appropriate therapy for diseases that are severely degenerative and may require medication or surgery. Many conditions of the spine are amenable to manipulative treatment, but this does not include **fractures**. The practitioner should be informed in advance if the patient is on anticoagulants, or has **osteoporosis** or any other condition that may weaken the bones. Other circumstances might suggest the patient should not have chiropractic care. These should be detected in the history or physical exam. In addition to fractures, **Down syndrome**, some congenital defects, and some types of cancer are a few of the things that may preclude spinal manipulation. On rare occasions, a fracture or dislocation may occur. There is also a very slim possibility of experiencing a **stroke** as a result of spinal manipulation, but estimates are that it is no more frequent than 2.5 occurrences per one million treatments.

Patients should be wary of chiropractors who insist on costly x rays and repeated visits with no end in sight. Extensive use is not scientifically justifiable, especially in most cases of lower back pain. There are some circumstances when x rays are indicated, including acute or possibly severe injuries such as those that might result from a car accident.

It is not uncommon to have local discomfort in the form of aches, pains, or spasms for a few days following a chiropractic treatment. Some patients may also experience mild headache or **fatigue** that resolves quickly.

Research and general acceptance

As recently as the 1970s, the American Medical Association (a national group of medical doctors) was quite hostile to chiropractic. AMA members were advised that it was unethical to be associated with chiropractors. Fortunately that has changed, and many allopathic or traditionally trained physicians enjoy cordial referral relationships with chiropractors. The public is strongly in favor of chiropractic treatment. Chiropractors see the lion's share of all patients who seek medical help for back problems, and chiropractic treatment is the most widely used of all alternative medical treatments.

WWW.BOOKBAZ.IR

KEY TERMS

Adjustment—A specific type of manipulation of the spine designed to return it to proper structural and functional form.

Allopathic—Conventional practice of medicine generally associated with M.D. physicians.

Dysmenorrhea—Painful menstruation.

Osteoporosis—A condition of decreased bone density, causing increased bone fragility, that is most common in elderly women.

Subluxation—Misalignment between vertebrae that structurally and functionally impairs nerve function.

Research has also supported the use of spinal manipulation for acute **low back pain**. There is some anecdotal evidence recommending chiropractic treatment for ailments unrelated to musculoskeletal problems, but there is not enough research-based data to support this. On the other hand, a chiropractor may be able to treat problems and diseases unrelated to the skeletal structure by employing therapies other than spinal manipulation.

Although many chiropractors limit their practice to spine and joint problems, others claim to treat disorders that are not closely related to the back or musculoskeletal system. These include **asthma**, bed-wetting, **bronchitis**, coughs, **dizziness**, dysmenorrhea, earache, **fainting**, headache, hyperactivity, **indigestion**, **infertility**, migraine, **pneumonia**, and issues related to **pregnancy**. There are at least three explanations for the possible effectiveness for these conditions. One is that the problem could be linked to a nerve impingement, as may be possible with bed-wetting, dizziness, fainting, and headache. In a second group, chiropractic treatment may offer some relief from complicating pain and spasms caused by the disease process, as with asthma, bronchitis, coughs, and pneumonia. The discomforts of pregnancy may also be relieved with gentle chiropractic therapy. A third possibility is that manipulation or use of soft-tissue techniques may directly promote improvement of some conditions. One particular procedure, known as the endonasal technique, is thought to help the eustachian tube to open and thus improve drainage of the middle ear. The tube is sometimes blocked off due to exudates or inflammatory processes. This can offer significant relief from earaches. Some headaches also fall in this category, as skilled use of soft tissue techniques and adjustment may relieve the muscle tension that may initiate some headaches.

Dysmenorrhea, hyperactivity, indigestion, and infertility are said to be relieved as a result of improved flow of blood and nerve energy following treatment. Evidence for this is anecdotal at best, but manipulation is unlikely to be harmful if causes treatable by other modalities have been ruled out.

For conditions such as cancer, fractures, infectious diseases, neurologic disease processes, and anything that may cause increased orthopedic fragility, chiropractic treatment alone is not an effective therapy, and may even be harmful in some cases. Those who have known circulatory problems, especially with a history of thrombosis, should not have spinal manipulation.

Chlamydial infections *see* **Chlamydial pneumonia; Epididymitis; Nongonococcal urethritis; Sexually transmitted diseases**

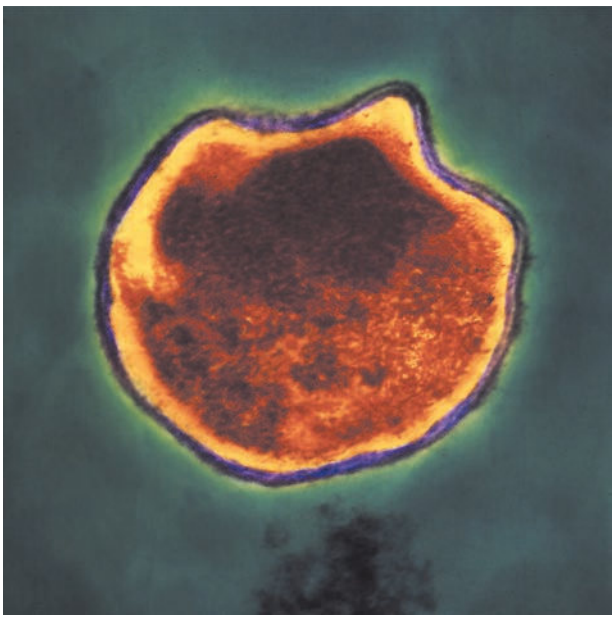
Chlamydial pneumonia

Definition

Chlamydial pneumonia refers to one of several types of pneumonia that can be caused by various types of the bacteria known as *Chlamydia*.

Description

Pneumonia is an infection of the lungs. The air sacs (alveoli) and/or the tissues of the lungs become swollen, and the alveoli may fill with pus or fluid. This prevents the lungs from taking in sufficient oxygen,



A transmission electron microscopy (TEM) of a sectioned *Chlamydia pneumonia* bacterium. *(Custom Medical Stock Photo, Inc.)*

which deprives the blood and the rest of the body's tissues of oxygen.

There are three major types of *Chlamydia*: *Chlamydia psittaci*, *Chlamydia pneumoniae*, and *Chlamydia trachomatis*. Each of these has the potential to cause a type of pneumonia.

Causes and symptoms

Chlamydia trachomatis is a major cause of sexually transmitted diseases (called nongonococcal urethritis and pelvic inflammatory disease). When a woman with an active chlamydial infection gives birth to a baby, the baby may aspirate (suck into his or her lungs) some of the mother's bacteria-laden secretions while passing through the birth canal. This can cause a form of relatively mild pneumonia in the newborn, occurring about two to six weeks after delivery.

Chlamydia psittaci is a bacteria carried by many types of birds, including pigeons, canaries, parakeets, parrots, and some gulls. Humans acquire the bacteria through contact with dust from bird feathers, bird droppings, or from the bite of a bird carrying the bacteria. People who keep birds as pets or who work where birds are kept have the highest risk for this type of pneumonia. This pneumonia, called psittacosis, causes fever, cough, and the production of sputum containing pus. This type of pneumonia may be quite severe, and is usually more serious in older patients. The illness can last several weeks.

Chlamydia pneumoniae usually causes a type of relatively mild "walking pneumonia." Patients experience fever and cough. This type of pneumonia is called a "community-acquired pneumonia" because it is easily passed from one member of the community to another.

Diagnosis

Laboratory tests indicating the presence of one of the strains of *Chlamydia* are sophisticated, expensive, and performed in only a few laboratories across the country. For this reason, doctors diagnose most cases of chlamydial pneumonia by performing a physical examination of the patient, and noting the presence of certain factors. For instance, if the mother of a baby sick with pneumonia is positive for a sexually transmitted disease caused by *Chlamydia trachomatis*, the diagnosis is obvious. History of exposure to birds in a patient sick with pneumonia suggests that *Chlamydia psittaci* may be the culprit. A mild pneumonia in an otherwise healthy person is likely to be a community-acquired walking pneumonia, such as that caused by *Chlamydia pneumoniae*.

Treatment

Treatment varies depending on the specific type of *Chlamydia* causing the infection. A newborn with *Chlamydia trachomatis* improves rapidly with erythromycin. *Chlamydia psittaci* infection is treated with tetracycline, bed rest, oxygen supplementation, and codeine-containing cough preparations. *Chlamydia pneumoniae* infection is treated with erythromycin.

Prognosis

The prognosis is generally excellent for the newborn with *Chlamydia trachomatis* pneumonia. *Chlamydia psittaci* may linger, and severe cases have a death rate of as high as 30%. The elderly are hardest hit by this type of pneumonia. A young, healthy person with *Chlamydia pneumoniae* has an excellent prognosis. In the elderly, however, there is a 5–10% death rate from this infection.

Prevention

Prevention of *Chlamydia trachomatis* pneumonia involves recognizing the symptoms of genital infection in the mother and treating her prior to delivery of her baby.

Chlamydia psittaci can be prevented by warning people who have birds as pets, or who work around

WWW.BOOKBAZ.IR

KEY TERMS

Alveoli—The small air sacs clustered at the ends of the bronchioles in the lungs, in which oxygen-carbon dioxide exchange takes place.

Aspiration—When solids or liquids that should be swallowed into the stomach are instead breathed into the respiratory system, or when substances from the outside environment are accidentally breathed into the lungs.

Sputum—Material produced within the alveoli in response to an infectious or inflammatory process.

birds, to be careful to avoid contact with the dust and droppings of these birds. Sick birds can be treated with an antibiotic in their feed. Because people can contract psittacosis from each other, a person sick with this infection should be kept in isolation, so as not to infect other people.

Chlamydia pneumoniae is difficult to prevent because it is spread by respiratory droplets from other sick people. Because people with this type of pneumonia do not always feel very sick, they often continue to attend school, go to work, and go to other public places. They then spread the bacteria in the tiny droplets that are released into the air during coughing. Therefore, this pneumonia is very difficult to prevent and often occurs in outbreaks within communities.

Choking

Definition

Choking is the inability to breathe because the trachea is blocked, constricted, or swollen shut.

Description

Choking is a medical emergency. When a person is choking, air cannot reach the lungs. If the airways cannot be cleared, death follows rapidly.

Anyone can choke, but choking is more common in children than in adults. Choking is a common cause of accidental death in young children who are apt to put toys or coins in their mouths, then unintentionally inhale them. About 3,000 adults die each year from choking on food.

People also choke because infection causes the throat tissue to swell shut. It is believed that this is what caused George Washington's death. Allergic reactions can also cause the throat to swell shut. Acute allergic reactions are called anaphylactic reactions and may be fatal. Strangulation puts external pressure on the trachea causing another form of choking.

Finally, people can choke from obstructive **sleep apnea**. This is a condition where tissues of the body obstruct the airways during sleep. Sleep apnea is most common in obese men who sleep on their backs. **Smoking**, heavy alcohol use, lung diseases such as **emphysema**, and an inherited tendency toward a narrowed airway and throat all increase the risk of choking during sleep.

Causes and symptoms

There are three reasons why people choke. These are:

- mechanical obstruction
- tissue swelling
- crushing of the trachea

Regardless of the cause, choking cuts off the air supply to the lungs. Indications that a person's airway is blocked include:

- the person cannot speak or cry out
- the person's face turns blue from lack of oxygen
- the person desperately grabs at his or her throat
- the person has a weak cough and labored breathing that produces a high-pitched noise
- the person has all of the symptoms previously mentioned, then becomes unconscious
- during sleep, the person has episodes of gasping, pauses in breathing, and sudden awakenings

Diagnosis

Diagnosing choking due to mechanical obstruction is straightforward, since the symptoms are obvious even to an untrained person. In choking due to infection, the person, usually a child, will have a **fever** and signs of illness before labored breathing begins. If choking is due to an allergic reaction to medication or insect bites, the person's earlobes and face will swell, giving an external sign that internal swelling is also occurring.

Choking due to sleep apnea is usually diagnosed on reports of symptoms by the person's sleep partner. There are also alarm devices to detect the occurrence of sleep apnea. Eventually sleep may be interrupted so frequently that daytime drowsiness becomes a problem.

Treatment

Choking, except during sleep apnea, is a medical emergency. If choking is due to allergic reaction or infection, people should summon emergency help or go immediately to an emergency room. If choking is due to obstructed airways, the **Heimlich maneuver** (an emergency procedure in which a person is grasped from behind in order to forcefully expel the obstruction) should be performed immediately. In severe cases a **tracheotomy** (an incision into the trachea through the neck below the larynx) must be performed.

Patients who suffer airway obstruction during sleep can be treated with a device similar to an oxygen mask that creates positive airway pressure and delivers a mixture of oxygen and air.

Prognosis

Many people are treated successfully for choking with no permanent effects. However, if treatment is unsuccessful, the person dies from lack of oxygen. In cases where the airway is restored after the critical period passes, there may be permanent brain damage.

Prevention

Watching children carefully to keep them from putting **foreign objects** in their mouth and avoiding giving young children food like raisins, round slices of hot dogs, and grapes can reduce the chance of choking in children. Adults should avoid heavy alcohol consumption when eating and avoid talking and laughing with food in their mouths. The risk of obstructive sleep apnea choking can be reduced by avoiding alcohol, tobacco smoking, tranquilizers, and sedatives before bed.

KEY TERMS

Trachea—The windpipe. A tube extending from below the voice box into the chest where it splits into two branches, the bronchi, that go to each lung.

Tracheotomy—The surgical creation of an opening in the trachea that functions as an alternative airway so that the patient may breathe.

Cholangitis

Definition

The term cholangitis means inflammation of the bile ducts. The term applies to inflammation of any portion of the bile ducts, which carry bile from the liver to the gallbladder and intestine. The inflammation is produced by bacterial infection or sometimes other causes.

Description

Bile, which is needed for digestion, is produced in the liver and then enters the common bile duct (CBD) through the hepatic ducts. Bile enters the gallbladder between meals, when the muscle or sphincter that controls flow of bile between the CBD and intestine is closed. During this period, bile accumulates in the CBD; the pressure in the CBD rises, as would a pipe closed off at one end. The increase in pressure eventually causes the bile to flow into the gallbladder. During meals, the gallbladder contracts and the sphincter between the gallbladder and intestine relaxes, permitting bile to flow into the intestine and take part in digestion.

WWW.BOOKBAZ.IR

Bile that has just been produced by the liver is sterile (free of bacteria). This is partly due to its antibacterial properties; these are produced by the immunoglobulins (antibodies) secreted in bile, the bile acids which inhibit bacterial growth themselves, and mucus.

A small number of bacteria may be present in the bile ducts and gallbladder, getting there by moving backward from the intestine, which unlike the bile ducts, contains large numbers of bacteria. The normal flow of bile out of the ducts and into the intestine also helps keep too many organisms from multiplying. Bacteria also reach the bile ducts from the lymph tissue or from the blood stream.

When the passage of bile out of the ducts is blocked, the few bacteria that are there rapidly reproduce. A partial blockage to the flow of bile can occur when a stone from the gallbladder blocks the duct, and also allows bacteria to flow back into the CBD, and creates ideal conditions for their growth. Tumors, on the other hand, cause a more complete blockage of bile flow, both in and out, so fewer infections occur. The reproducing organisms are often able to enter the bloodstream and infect multiple organs such as the liver and heart valves.

Another source of inflammation of the bile ducts occurs in diseases of altered immunity, known as "autoimmune diseases." In these diseases, the body fails to recognize certain cells as part of its normal composition. The body thinks these cells are foreign and produces antibodies to fight them off, just as it fights against bacteria and viruses. Primary sclerosing cholangitis is a typical example of an autoimmune disease involving the bile ducts.

Causes and symptoms

As noted previously, the two things that are needed for cholangitis to occur are: 1) obstruction to bile flow, and 2) presence of bacteria within the bile ducts. The most common cause of cholangitis is infection of the bile ducts due to blockage by a gallstone. Strictures (portions of ducts that have become narrow) also function in the same way. Strictures may be due to congenital (birth) abnormalities of the bile ducts, form as a result of injury to the bile duct (such as surgery, **trauma**), or result from inflammation that leads to scar tissue and narrowing.

The bacterium most commonly associated with infection of the bile ducts is *Escherichia coli* (*E. coli*) which is a normal inhabitant of the intestine. In some cases, more than one type of bacteria is involved. Patients with **AIDS** can develop infection of narrowed bile ducts with unusual organisms such as *Cryptosporidium* and others.

The three symptoms present in about 70% of patients with cholangitis are abdominal **pain**, **fever**, and **jaundice**. Some patients only have chills and fever with minimal abdominal symptoms. Jaundice or yellow discoloration of the skin and eyes occurs in about 80% of patients. The color change is due to bile pigments that accumulate in the blood and eventually in the skin and eyes.

Inflammation due to the autoimmune disease primary sclerosing cholangitis leads to multiple areas of narrowing and eventual infection. Tumors can block the bile duct and also cause cholangitis, but as noted, infection is relatively infrequent; in fact cholangitis occurs in only about one in six patients with tumors.

Another type of bile duct infection occurs mainly in Southeast Asia and is known as recurrent pyogenic cholangitis or Oriental cholangitis. It has also been identified in Asians immigrating to North America. Most patients have stones in the bile ducts and/or gallbladder, and many cases are associated with the presence of parasites within the ducts. The role of parasites in causing infection is not clear. Many researchers believe that they are just coincidental, and have nothing to do with the stones or infection.

Diagnosis

The symptoms mentioned previously are alone very suggestive of cholangitis; however, it is important to determine the exact cause and site of possible obstruction. This is because attacks are likely to recur, and different causes require different treatments. For example, the treatment of cholangitis due to a stone in the CBD is different from that due to bile duct strictures. An elevated white blood count suggests infection, but may be normal in 20% of patients. Abnormal or elevated tests of liver function, such as bilirubin and others are also frequently present. The specific bacteria is sometimes identified from blood cultures.

X-ray techniques

A number of x-ray techniques can assist in confirming the diagnosis of bile duct obstruction; these include **ultrasound** and **computed tomography scans** (CT scans). However, ultrasound often cannot tell if an obstruction is due to a stricture or stone, missing a

KEY TERMS

Antibiotic—A medication that is designed to kill or weaken bacteria.

Bilirubin—A pigment produced by the liver that is excreted in bile which causes a yellow discoloration of the skin and eyes when it accumulates in those organs. Bilirubin levels can be measured by blood tests, and are most often elevated in patients with liver disease or a blockage to bile flow.

Computed tomography scan (CT scan)—A specialized x-ray procedure in which cross-sections of the area in question can be examined in detail. In evaluating the bile ducts, iodine-based dye is often injected intravenously. The procedure is of greatest value in diagnosing the complications of gallstones (such as abscesses, pancreatitis) rather than documenting the presence of a stone.

Endoscope—An endoscope as used in the field of gastroenterology is a thin flexible tube which uses a lens or miniature camera to view various areas of the gastrointestinal tract. When the procedure is performed to examine certain organs such as the bile ducts or pancreas, the organs are not viewed directly, but rather indirectly through the injection of x-ray dye into the bile duct.

Endoscopy—The performance of an exam using an endoscope is referred by the general term endoscopy. Diagnosis through biopsies or other means and therapeutic procedures can be done with these instruments.

Primary sclerosing cholangitis—A chronic disease in which it is believed that the immune system fails to recognize the cells that compose the bile ducts as part of the same body, and attempts to destroy them. It is not clear what exactly causes the disease, but it is frequently associated with another inflammatory disease of the digestive tract, ulcerative colitis. The inflammation of the ducts eventually produces formation of scar tissue, causing multiple areas of narrowing (strictures) that block bile flow and lead to bacterial infection. Liver transplant gives the best chance for long-term survival.

Ultrasound—A non-invasive procedure based on changes in sound waves of a frequency that cannot be heard, but respond to changes in tissue composition. It requires no preparation and no radiation occurs. It has become the "gold standard" for diagnosis of stones in the gallbladder, but is less accurate in diagnosing stones in the bile ducts. Gallstones as small as 2 mm can be identified. The procedure can now also be done through an endoscope, greatly improving investigation of the bile ducts.

stone in about half the cases. CT scans have an even poorer record of stone detection.

Another method of diagnosing and sometimes treating the cause of bile duct obstruction or narrowing is called **percutaneous transhepatic cholangiography**. In this procedure, dye is injected into the ducts by means of a needle placed into the liver. It is also used to drain bile and relieve an obstruction.

A newer imaging technique, magnetic resonance cholangiopancreatogrpay (MRCP), may be used to determine the presence of CBD stones when other imaging techniques are inconclusive.

ENDOSCOPIC TECHNIQUES. An endoscope is a thin flexible tube that uses a lens or mirror to look at various parts of the gastrointestinal tract. **Endoscopic retrograde cholangiopancreatography** (ERCP) can accurately determine the cause and site of blockage. It also has the advantage of being able to treat the cause of obstruction, by removing stones and dilating (stretching) strictures. ERCP involves the injection of x-ray dye into the bile ducts through an endoscope. **Endoscopic ultrasound** is another endoscopic alternative, but is not as available as ERCP and is not therapeutic.

Treatment

The first aim is to control the bacterial infection. Broad-spectrum **antibiotics** are usually administered. Eighty percent of patients respond promptly to conservative treatment with antibiotic therapy. If the infection does not come under control promptly (usually within 24 hours), as noted by decrease in fever and pain, then other methods to relieve the obstruction and infection will be needed. Either way, definitive treatment of the cause of bile duct infection is the next step, and this has undergone revolutionary changes in the past decade. Endoscopic, radiographic and other techniques have made it possible to successfully remove stones and dilate strictures that previously required surgical intervention, often with high morbidity and mortality.

WWW.BOOKBAZ.IR

Radiologic and endoscopic techniques

Just as with diagnosis, treatment of cholangitis involves a number of similar procedures that differ mainly in the way the bile ducts are entered. The aims of these techniques are immediate relief of obstruction and infection as well as correction of any abnormalities that have caused them. It is important to realize that even with **endoscopy**, x-ray dye is injected into the ducts and therefore the radiologist plays a role in both types of procedures. When endoscopy is used, the muscle between the intestine and bile duct is widened, to allow stones to pass. This is called a sphincterotomy and is often enough to relieve any obstruction and help clear infection. The widening of the muscle is needed if other procedures involving the bile duct are going to be performed. **Endoscopic sphincterotomy** with extraction of **gallstones** and/or insertion of a stent is now the treatment of choice for re-establishing biliary drainage in acute cholangitis. Common bile duct stones can be removed in most patients (up to 95% of patients) after the obstruction is removed with sphincterotomy.

The techniques mentioned previously can be summarized as follows:

- Insertion of a catheter or thin flexible tube to drain bile and relieve obstruction. When performed by insertion of a needle into the liver the technique is called percutaneous transhepatic biliary drainage (PTBD); when performed endoscopically the catheter exits through the nose and is called a nasobiliary drain.
- Balloons can be inserted into the ducts with either method to dilate strictures.
- Insertion of a prosthesis which is a rigid or flexible tube designed to keep a narrowed area open; it is usually placed after a stricture is dilated with a balloon.

Surgical treatment

Fortunately, with recent advances in the methods mentioned previously, this is a last option. Nonetheless, about 5–10% of patients will need to undergo surgical exploration of the bile ducts.

In some instances, the bile duct is so narrowed due to prior inflammation or tumor, that it needs connection to a different area of the intestinal tract to drain. This is rather complicated surgery and carries a mortality rate of 2%.

Prognosis

The outlook for those with cholangitis has markedly improved in the last several years due in large part to the development of the techniques described previously. For those patients whose episode of infection is caused by something other than a simple stone, the future is not as bright, but still often responsive to treatment. Some patients with autoimmune disease will need **liver transplantation**.

Prevention

This involves eliminating those factors that increase the risk of infection of the bile ducts, mainly stones and strictures. If it is medically possible, patients who have their gallbladder and suffer a bout of cholangitis should undergo surgical removal of the gallbladder and removal of any stones.

For other patients, a variety of therapies as outlined previously, including dissolving small stones with bile acids are also available. A combination of several of these methods is needed in some patients. Patients should discuss the risks and alternatives of these treatments with their physicians.

Cholecystectomy

Definition

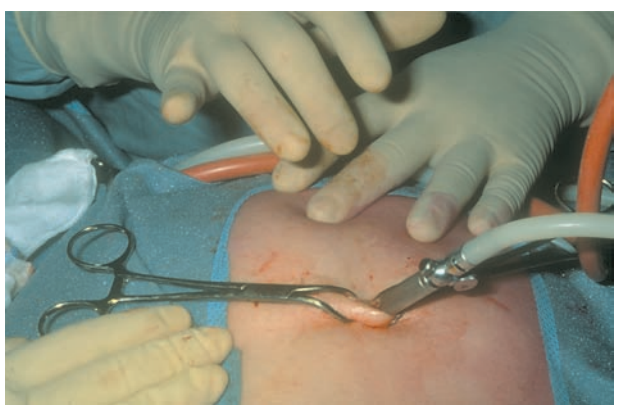
A cholecystectomy is the surgical removal of the gallbladder. The two basic types of this procedure are open cholecystectomy and the laparoscopic approach. It is estimated that the laparoscopic procedure is currently used for approximately 80% of cases.

Purpose

A cholecystectomy is performed to treat cholelithiasis and **cholecystitis**. In cholelithiasis, **gallstones** of varying shapes and sizes form from the solid components of bile. The presence of these stones, often referred to as gallbladder disease, may produce symptoms of excruciating right upper abdominal **pain** radiating to the right shoulder. The gallbladder may become the site of acute infection and inflammation, resulting in symptoms of upper right abdominal pain, nausea, and **vomiting**. This condition is referred to as cholecystitis. The surgical removal of the gallbladder can provide relief of these symptoms. Cholecystectomy is used to treat both acute and chronic cholecystitis when there are significant pain symptoms. The typical composition of gallstones is predominately **cholesterol**, or a compound called **calcium** bilirubinate.

Cholelithiasis

Most patients with cholelithiasis have no significant physical symptoms. Approximately 80% of gallstones do not cause significant discomfort. Patients who develop biliary **colic** generally do have some symptoms. When gallstones obstruct the cystic duct, intermittent, extreme, cramping pain typically develops in the right upper quadrant of the abdomen. This pain generally occurs at night and can last from a few minutes to several hours. An acute attack of cholecystitis is often associated with the consumption of a large, high-fat meal.



A surgeon performs a laparoscopic cholecystectomy on a patient. *(Custom Medical Stock Photo, Inc.)*

The medical management of gallstones largely depends on the presentation of the patient. Patients with no symptoms generally do not require any medical treatment. The best treatment for patients with symptoms is usually surgery. Laparoscopic cholecystectomy is typically preferred over the open surgical approach because of the decreased recovery period. Patients who are not good candidates for either type of surgery can obtain some symptom relief with drugs, especially oral bile salts.

Cholecystitis

Cholecystitis is an inflammation of the gallbladder, both acute and chronic, that results after the development of gallstones in some individuals. The most common symptoms and physical findings associated with cholecystitis include:

- pain and tenderness in the upper right quadrant of the abdomen
- nausea
- vomiting
- fever
- jaundice
- history of pain after eating large, high-fat meals

Demographics

Overall, cholelithiasis is found in about 20,000,000 Americans. An overwhelming majority of these individuals do not ever develop symptoms. Overall, about 500,000–600,000 (2–3%) are treated with cholecystectomies every year. Typically, the incidence of cholelithiasis increases with age. The greatest incidence occurs in individuals between the ages of 40 and 60 years. The following groups are at an increased risk for developing cholelithiasis:

- pregnant women
- females
- family history of gallstones
- obesity
- certain types of intestinal disease
- age greater than 40 years
- oral contraceptive use
- diabetes mellitus
- estrogen replacement therapy
- rapid weight loss

WWW.BOOKBAZ.IR

KEY TERMS

Cholecystitis—Infection and inflammation of the gallbladder, causing severe pain and rigidity in the upper right abdomen.

Cholelithiasis—Also known as gallstones, these hard masses are formed in the gallbladder or passages, and can cause severe upper right abdominal pain radiating to the right shoulder, as a result of blocked bile flow.

Gallbladder—A hollow pear-shaped sac on the under surface of the right lobe of the liver. Bile comes to it from the liver, and passes from it to the intestine to aid in digestion.

Laparoscope—A device consisting of a tube and optical system for observing the inside of the abdomen and its organs.

Overall, patients with cholelithiasis have about a 20% chance of developing biliary colic (the extremely painful complication that usually requires surgery) over a 20-year period.

Acute cholecystitis develops most commonly in women between the ages of 40 and 60 years. Some ethnic groups, such as Native Americans, have a dramatically higher incidence of cholecystitis.

Description

Cholecystectomy, including the laparoscopic approach, is usually performed by a general surgeon who has completed a five-year residency training program in all components of **general surgery** and, in particular, proper techniques involving the use of the laparoscope. If surgery is being considered, it is a good idea to find out how many laparoscopic cholecystectomies the surgeon performs on a yearly basis. Laparoscopic cholecystectomies are often performed in the specialized department of a general hospital, but they are also performed in specialized gastrointestinal clinics or institutes for gastrointestinal disorders.

The laparoscopic cholecystectomy involves the insertion of a long, narrow cylindrical tube with a camera on the end, through an approximately 0.4 in. (1 cm) incision in the abdomen, which allows visualization of the internal organs and projection of this image onto a video monitor. Three smaller incisions allow for insertion of other instruments to perform the surgical procedure. A laser may be used for the incision and cautery (burning unwanted tissue to stop bleeding), in which case the procedure may be called laser laparoscopic cholecystectomy.

In a conventional or open cholecystectomy, the gallbladder is removed through a surgical incision high in the right abdomen, just beneath the ribs. A drain may be inserted to prevent accumulation of fluid at the surgical site.

Diagnosis

The initial diagnosis of acute cholecystitis is based on the following symptoms:

- constant, dull pain in upper right quadrant of abdomen
- fever
- chills
- nausea
- vomiting
- pain aggravated by moving or coughing

Most patients have elevated leukocyte (white blood cells) levels. Leukocyte levels are determined using laboratory analysis of blood samples. Traditional x rays are not particularly useful in diagnosing cholecystitis. Ultrasonography of the gallbladder usually provides evidence of gallstones, if they are present. Ultrasonography can also help identify inflammation of the gallbladder. Nuclear imaging may also be used. This type of imaging cannot identify gallstones, but it can provide evidence of obstruction of the cystic and common bile ducts.

Cholelithiasis is initially diagnosed based on the following signs and symptoms:

- history of biliary colic or jaundice
- nausea
- vomiting
- sudden onset of extreme pain in the upper right quadrant of the abdomen
- fever
- chills

Laboratory blood analysis often finds evidence of elevated bilirubin, alkaline phosphatase, or aminotransferase levels. Ultrasonography, computed tomography (CT) scanning, and radionuclide imaging are able to detect the impaired functioning of bile flow and of the bile ducts.

Preparation

As with any surgical procedure, the patient will be required to sign a consent form after the procedure is explained thoroughly. Food and fluids will be

prohibited after midnight before the procedure. **Enemas** may be ordered to clean out the bowel. If nausea or vomiting are present, a suction tube to empty the stomach may be used, and for laparoscopic procedures, a urinary drainage catheter will also be used to decrease the risk of accidental puncture of the stomach or bladder with insertion of the trocar (a sharp, pointed instrument).

Aftercare

Postoperative care for the patient who has had an open cholecystectomy, as with those who have had any major surgery, involves monitoring of blood pressure, pulse, respiration, and temperature. Breathing tends to be shallow because of the effect of **anesthesia**, and the patient's reluctance to breathe deeply due to the pain caused by the proximity of the incision to the muscles used for respiration. The patient is shown how to support the operative site when breathing deeply and coughing and is given pain medication as necessary. Fluid intake and output is measured, and the operative site is observed for color and amount of wound drainage. Fluids are given intravenously for 24–48 hours, and then the patient's diet is gradually advanced as bowel activity resumes. The patient is generally encouraged to walk eight hours after surgery and discharged from the hospital within three to five days, with return to work approximately four to six weeks after the procedure.

Care received immediately after laparoscopic cholecystectomy is similar to that of any patient undergoing surgery with general anesthesia. A unique postoperative pain may be experienced in the right shoulder related to pressure from carbon dioxide used in the laparoscopic tubes. This pain may be relieved by lying down on the left side with right knee and thigh drawn up to the chest. Walking will also help increase the body's reabsorption of the gas. The patient is usually discharged the day after surgery and allowed to shower on the second postoperative day. The patient is advised to gradually resume normal activities over a three-day period, while avoiding heavy lifting for about ten days.

Risks

Potential problems associated with open cholecystectomy include respiratory problems related to location of the incision, wound infection, or **abscess** formation. Possible complications of laparoscopic cholecystectomy include accidental puncture of the bowel or bladder and uncontrolled bleeding. Incomplete reabsorption of the carbon dioxide gas could irritate the muscles used in respiration and cause respiratory distress. While most patients with acute cholecystitis respond well to the laparoscopic technique, about 5%–30% of these patients require a conversion to the open technique because of complications. Some patients undergoing elective laparoscopic cholecystectomy will require conversion to an open procedure.

The complication rate is less than 0.5% with open cholecystectomy and about 1% with laparoscopic cholecystectomy. The primary complication with the open technique is infection, whereas bile leak and hemorrhage are the most common complications associated with the laparoscopic technique. The overall mortality rate associated with cholecystectomy is less than 1%; however, the rate of mortality in the elderly is higher.

In a small minority of cases, symptoms will persist in patients who receive cholecystectomy. This has been named the post-cholecystectomy syndrome, and usually results from functional bowel disorder, errors in diagnosis, technical errors, overlooked common bile duct stones, recurrence of common bile duct stones, or the spasm of a structure called the sphincter of Oddi.

Results

The prognosis for cholecystitis and cholelithiasis patients who receive cholecystectomy is generally good. Overall, cholecystectomy relieves symptoms in about 95% of cases.

Alternatives

Acute cholecystitis usually improves following conservative therapy in most patients. This conservative therapy involves the withholding of oral feedings, the use of intravenous feedings, and the administration of **antibiotics** and **analgesics**. This is only a short-term alternative in hospitalized patients. Most of these patients should receive cholecystectomy within a few days to prevent recurrent attacks. In the short term, patients often receive narcotic analgesics such as meperidine to relieve the intense pain associated with this condition. Patients who have evidence of gallbladder perforation or **gangrene** need to have an immediate cholecystectomy.

In patients with cholelithiasis who are deemed unfit for surgery, alternative treatments are sometimes effective. These individuals often have symptom improvement after lifestyle changes and medical therapy. Lifestyle changes include dietary avoidance of foods high in polyunsaturated fats and gradual weight loss in obese individuals. Medical therapy includes the administration of oral bile salts. Patients with three or fewer gallstones of cholesterol composition and with a

WWW.BOOKBAZ.IR

gallstone diameter less than 0.6 in. (15 mm) are more likely to receive medical therapy and have positive results. The primary requirements for receiving medical therapy include the presence of a functioning gallbladder and the absence of calcification on CT scans. Other nonsurgical alternatives include using a solvent to dissolve the stones and using sound waves to break up small stones. A major drawback to medical therapy is the high recurrence rate of stones in those treated, as well as the possibility of successfully removing stones, but leaving an infected gallbladder behind, requiring a later operation for its removal.

Mark Mitchell

REVISED BY ROSALYN CARSON-DEWITT, MD

Cholecystitis

Definition

Cholecystitis refers to a painful inflammation of the gallbladder's wall. The disorder can occur a single time (acute), or can recur multiple times (chronic).

Description

The gallbladder is a small, pear-shaped organ in the upper right hand corner of the abdomen. It is connected by a series of ducts (tube-like channels) to the liver, pancreas, and duodenum (first part of the small intestine). To aid in digestion, the liver produces a substance called bile, which is passed into the gallbladder. The gallbladder concentrates this bile, meaning that it reabsorbs some of the fluid from the bile to make it more potent. After a meal, bile is squeezed out of the gallbladder by strong muscular contractions, and passes through a duct into the duodenum. Due to the chemical makeup of bile, the contents of the duodenum are kept at an optimal pH level for digestion. The bile also plays an important part in allowing fats within the small intestine to be absorbed.

A close-up view of an inflamed gallbladder. *(Custom Medical Stock Photo, Inc.)*

Demographics

Gallstone formation is seen in twice as many women as men, particularly those between the ages of 20 and 60. Pregnant women or those on birth control pills or estrogen replacement therapy have a greater risk of **gallstones**, as do Native Americans and Mexican Americans.

Risk factors

People who are overweight, or who lose a large amount of weight quickly, are at greater risk for developing gallstones. Not all individuals with gallstones go on to have cholecystitis, since many people never have any symptoms from their gallstones and never know they exist. However, the vast majority of people with cholecystitis are found to have gallstones. Rare causes of cholecystitis include severe **burns** or injury, massive systemic infection, severe illness, diabetes, obstruction by a tumor of the duct leaving the gallbladder, and certain uncommon infections of the gallbladder (including bacteria and worms).

Causes and symptoms

In about 95% of all cases of cholecystitis, the gallbladder contains gallstones. Gallstones are solid accumulations of the components of bile, particularly **cholesterol**, bile pigments, and **calcium**. These solids may occur when the components of bile are not in the correct proportion to each other. If the bile becomes overly concentrated, or if too much of one component is present, stones may form. When these stones block the duct leaving the gallbladder, bile accumulates within the gallbladder. The gallbladder continues to contract, but the bile cannot pass out of the gallbladder in the normal way. Back pressure on the gallbladder, chemical changes from the stagnating bile trapped within the gallbladder, and occasionally bacterial infection result in damage to the gallbladder wall. As the gallbladder becomes swollen, some areas of the wall do not receive adequate blood flow, and lack of oxygen causes cells to die.

When the stone blocks the flow of bile from the liver, certain normal byproducts of the liver's processing of red blood cells (called bilirubin) build up. The bilirubin is reabsorbed into the bloodstream, and over time this bilirubin is deposited in the skin and in the whites of the eyes. Because bilirubin contains a yellowish color, it causes a yellowish cast to the skin and eyes that is called **jaundice**.

Although there are rare reports of patients with chronic cholecystitis who never experience any **pain**, nearly 100% of the time cholecystitis is diagnosed after a patient has experienced a bout of severe pain in the region of the gallbladder and liver. The pain may be crampy and episodic, or it may be constant. The pain is often described as pushing through to the right upper back and shoulder. Because deep breathing increases the pain, breathing becomes shallow. **Fever** is often present, and **nausea and vomiting** are nearly universal. Jaundice occurs when the duct leaving the liver is also obstructed, although it may take a number of days for it to become apparent. When bacterial infection sets in, the patient may begin to experience higher fever and shaking chills.

Diagnosis

Examination

Diagnosis of cholecystitis involves a careful abdominal examination. The enlarged, tender gallbladder may be felt through the abdominal wall. Pressure in the upper right corner of the abdomen may cause the patient to stop breathing in, due to an increase in pain. This is called Murphy's sign. **Physical examination** may also reveal an increased heart rate and an increased rate of breathing.

Tests

Blood tests will show an increase in the white blood count and bilirubin. **Ultrasound** is used to look for gallstones and to measure the thickness of the gallbladder wall (a marker of inflammation and scarring). A scan of the liver and gallbladder, with careful attention to the system of ducts throughout (called the biliary tree) is used to demonstrate obstruction of ducts.

Rare complications of cholecystitis include:

- massive infection of the gallbladder, in which the gallbladder becomes filled with pus (called empyema)
- perforation of the gallbladder, in which the build-up of material within the gallbladder becomes so great that the wall of the organ bursts, with a resulting abdominal infection called peritonitis
- formation of abnormal connections between the gallbladder and other organs (the duodenum, large intestine, stomach), called fistulas
- obstruction of the intestine by a very large gallstone (called gallstone ileus)
- emphysema of the gallbladder, in which certain bacteria that produce gas infect the gallbladder, resulting in stretching of the gallbladder and disruption of its wall by gas

WWW.BOOKBAZ.IR

KEY TERMS

Bile—A substance produced by the liver, and concentrated and stored in the gallbladder. Bile contains many different substances, including bile salts, cholesterol, and bilirubin. After a meal, the gallbladder pumps bile into the duodenum (the first part of the small intestine) to keep the intestine's contents at the appropriate pH for digestion, and to help break down fats.

Bilirubin—Produced when red blood cells break down. It is a yellowish color and when levels are abnormally high, it causes the yellowish tint to eyes and skin known as jaundice.

Cholecystectomy—An operation to remove the gallbladder.

Cholecystotomy—An operation during which the gallbladder is opened, gallstones are removed, and excess bile is drained. The gallbladder is not removed.

Duct—A tube through which various substances can pass. These substances can travel through ducts to another organ or into the bloodstream.

Treatment

Initial treatment of cholecystitis usually requires hospitalization. The patient is given fluids, salts, and sugars through a needle placed in a vein (intravenous or IV). No food or drink is given by mouth. A tube, called a nasogastric or NG tube, may need to be passed through the nose and down into the stomach to drain out the excess fluids. Medications for pain and IV administration of broad spectrum **antibiotics** are initiated.

Treatment almost always involves removal of the gallbladder, a surgery called **cholecystectomy**. It is not usually recommended that the patient have surgery while acutely ill, however, patients with complications may require emergency surgery (immediately following diagnosis) because the death rate increases in these cases. Similarly, patients who have cholecystitis with no gallstones have a 50% chance of death if the gallbladder is not quickly removed. Most patients do best if surgery is performed after they have been stabilized with fluids, possibly an NG tube, and administration of antibiotics. Results of recent research indicate that early operation (laparoscopic cholecystectomy) by an experienced surgeon within 72 hours of admission results in the best outcomes for the patient. In patients who have other serious medical problems that may increase the risks of gallbladder removal surgery, the surgeon may decide to leave the gallbladder in place. In this case, the operation may involve removing obstructing gallstones and draining infected bile (called cholecystotomy).

Both cholecystectomy and cholecystotomy may be performed via the classical open abdominal operation (laparotomy). Tiny, "keyhole" incisions, a flexible scope, and a laser device that shatters the stones (a laparoscopic laser) can be used to destroy the gallstones. The laparoscopic procedure can also be used to remove the gallbladder through one of the small incisions. Because of the smaller incisions, laparoscopic cholecystectomy is a procedure that is less painful and promotes faster healing.

Prognosis

Hospital management of cholecystitis ends the symptoms for about 75% of all patients. Of these patients, 25% will have another attack of cholecystitis within a year, and 60% will have another attack within six years. Each attack of cholecystitis increases a patient's risk of developing life-threatening complications, requiring emergency surgery. Therefore, early removal of the gallbladder, rather than a "wait-and-see" approach, is usually recommended. Cure is complete in those patients who undergo cholecystectomy.

Prevention

Prevention of cholecystitis is best attempted by maintaining a reasonable ideal weight. Some studies have suggested that eating a diet high in fiber, vegetables, and fruit is also protective.

Cholera

Definition

Cholera is a serious, acute, **infectious disease** characterized by watery **diarrhea** that is caused by the bacterium *Vibrio cholerae*. It was first identified by Robert Koch in 1883 during a cholera outbreak in Egypt. The name of the disease comes from a Greek word meaning "flow of bile."

Description

Cholera is spread by eating food or drinking water that has been contaminated with *V. cholerae*. Contamination usually occurs when human feces from a person who has the disease seeps into a community water supply. Fruits and vegetables also can be contaminated in areas where crops are fertilized with human feces. Cholera bacteria live in warm, brackish water and can infect persons who eat raw or undercooked seafood obtained from such waters. In the United States, 4 cases of cholera in Louisiana were attributed to undercooked seafood taken from contaminated waters following hurricanes Katrina and Rita. Cholera is rarely transmitted directly from one person to another.

A false color transmission electron micrograph (TEM) of *Vibrio cholerae bacterium* magnified 6,000 times its original size. *(Custom Medical Stock Photo, Inc.)*

Because of an extensive system of sewage and water treatment in the United States, Canada, European countries, Japan, and Australia, cholera is not a concern for visitors and residents of these countries. However, people visiting or living in other parts of the world, particularly Haiti, the Indian subcontinent, and parts of Africa and South America, should be aware of the potential for contracting cholera and practice prevention. Fortunately, the disease is both preventable and treatable. Deaths usually occur in developing countries because of lack of access to hospitals and treatment.

Risk factors

Some people are at greater risk of having a severe case of cholera if they become infected. These risk factors include:

- taking proton pump inhibitors, histamine (H2) blockers, or antacids to control acid indigestion. As noted earlier, *V. cholerae* is sensitive to stomach acid.
- having had chronic gastritis caused by infection with *Helicobacter pylori*
- having had a partial gastrectomy (surgical removal of a portion of the stomach)
- being of a certain age group, such as infants, children, and the elderly

Demographics

Although cholera was a **public health** problem in the United States and Europe a hundred years ago, modern sanitation and the treatment of drinking water have virtually eliminated the disease in developed countries. In the United States, the rate is about 1 case per 1,000,000 population and in travelers returning from abroad about 1 case per 500,000 population.

Internationally, cholera outbreaks continue to occur in less developed countries, particularly following such natural disasters as hurricanes and tsunamis during which water supplies become contaminated. A particularly severe outbreak occurred in Haiti beginning in mid-October 2010. As of June 2011, more than 336,000 cases of cholera resulting in more than 5,500 deaths had been reported. The epidemic continued through 2014 and into 2015.

WHO estimates that between 3 and 5 million cases of cholera occur each year accounting for 100,000–120,000 deaths. This is only an estimate because

WWW.BOOKBAZ.IR

WHO believes that the number of reported cases represents only 5% 10% of actual cases. In areas where cholera occurs, it is the most feared epidemic diarrheal disease because people can die within hours of infection from **dehydration** that results from severe diarrhea.

Cholera often occurs in major outbreaks or epidemics; seven pandemics (countrywide or worldwide epidemics) of cholera were recorded between 1817 and 2014. WHO estimates that during any cholera epidemic, approximately 0.2–1% of the local population will contract the disease.

Anyone can get cholera, but infants, children, pregnant women, and the elderly are more likely to die from the disease because they become dehydrated faster than other individuals. There is no particular season in which cholera is more likely to occur.

Causes and symptoms

Cholera is caused by the bacterium *V. cholerae*. This bacterium is a gram-negative aerobic bacillus, or rod-shaped bacterium. It has two major biotypes: O1 and O139. The 01 biotype is responsible for most outbreaks. The 0139 biotype is found only in Southeast Asia.

Because *V. cholerae* is sensitive to acid, most cholera-causing bacteria die in the acidic environment of the stomach. However, when a person has ingested food or water containing large amounts of cholera bacteria, some will survive to infect the intestines. As would be expected, antacid usage or the use of any medication that blocks or reduces acid production in the stomach allows more bacteria to survive and cause infection.

In the small intestine, the rapidly multiplying bacteria produce a toxin that causes a large volume of water and electrolytes to be secreted into the bowels and then to be abruptly eliminated in the form of watery diarrhea. **Vomiting** may also occur. Symptoms begin to appear between one and three days after contaminated food or water has been ingested.

Most cases of cholera are mild, but about one in 20 patients experience severe, potentially life-threatening symptoms. In severe cases, fluids can be lost through diarrhea and vomiting at the rate of one quart per hour. This loss of fluid can produce a dangerous state of dehydration unless the lost fluids and electrolytes are rapidly replaced.

Signs of dehydration include intense thirst, little or no urine output, dry skin and mouth, an absence of tears, glassy or sunken eyes, **muscle cramps**, weakness, and rapid heart rate. The fontanelle (soft spot on an infant's head) will appear to be sunken or drawn in. Dehydration occurs most rapidly in the very young and the very old because they have fewer fluid reserves. A doctor should be consulted immediately any time signs of severe dehydration occur. Immediate replacement of lost fluids and electrolytes is necessary to prevent kidney failure, **coma**, and death.

Diagnosis

Tests

Rapid diagnosis of cholera can be made by examining a fresh stool sample under the microscope for the presence of *V. cholerae* bacteria. Cholera can also be diagnosed by culturing a stool sample in the laboratory to isolate the cholera-causing bacteria. In addition, a blood test may reveal the presence of antibodies against the cholera bacteria. Because of the speed at which life-threatening dehydration can occur, in areas where cholera occurs often, however, patients are usually treated without laboratory confirmation for diarrhea and vomiting symptoms as if they had cholera.

Treatment

The key to treating cholera lies in preventing dehydration by replacing fluids and electrolytes lost through diarrhea and vomiting. The discovery that rehydration can be accomplished orally revolutionized the treatment of cholera and other, similar diseases by making this simple, cost-effective treatment widely available throughout the world. WHO has developed an inexpensive oral replacement fluid containing appropriate amounts of water, sugar, and salts that is used worldwide. In cases of severe dehydration, replacement fluids must be given intravenously. The death rate for patients with access to intravenous fluid replacement is about 1%. Patients should be encouraged to drink when they can keep liquids down and eat when their appetite returns. Recovery generally takes three to six days.

Drugs

Adults may be given the **antibiotics** to shorten the duration of the illness and reduce fluid loss. WHO recommends antibiotic treatment only in cases of severe dehydration. If antibiotics are overused, the cholera bacterium may develop drug resistance, making commonly used antibiotics ineffective in treating even severe cases of cholera.

Tetracycline is the most common antibiotic given to adults. Other antibiotics that may be given to speed up the clearance of *V. cholerae* from the body include azithromycin (Zithromax), doxycycline (Bio-

KEY TERMS

Bacillus—A rod-shaped bacterium. The organism that causes cholera is a gram-negative bacillus.

Biotype—A variant strain of a bacterial species with distinctive physiological characteristics.

Electrolytes—Salts and minerals that ionize in body fluids. Common human electrolytes are sodium, chloride, potassium, and calcium. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Pandemic—A widespread epidemic that affects whole countries or the entire world. There have been seven cholera pandemics since 1817.

Toxin—A poison, in the case of cholera, a poison secreted as a byproduct of the growth of the cholera bacteria in the small intestine.

Tab, doryx, Vibramycin), ciprofloxacin (Cipro), and erythromycin.

Alternatives

A possible complementary treatment for fluid loss caused by cholera is a plant-derived compound, an extract made from the tree bark of *Croton lechleri*, the Sangre de grado tree found in the South American rain forest. Researchers at a hospital research institute in California reported that the extract appears to work by preventing the loss of chloride and other electrolytes from the body. However, this herbal treatment is no substitute for oral hydration therapy in moderate to severe cases.

Prognosis

Cholera is a very treatable disease so long as resources are available for rehydration. Patients with milder cases of cholera usually recover on their own in three to six days without additional complications. They may eliminate the bacteria in their feces for up to two weeks. Chronic carriers of the disease are rare. With prompt fluid and electrolyte replacement, the death rate in patients with severe cholera is less than 1%. Untreated, the death rate can be greater than 50%. The difficulty in treating severe cholera does not lie in not knowing how to treat it but rather in getting medical care to the sick in developing areas of the world where medical resources are limited.

Prevention

The best form of cholera prevention is to establish good sanitation and waste treatment systems. In the absence of adequate sewage treatment, the following guidelines should be followed to reduce the possibility of infection:

- Boil water. Drink and brush teeth only with water that has been boiled or treated with chlorine or iodine tablets. Safe drinks include coffee and tea made with boiling water or carbonated bottled water and carbonated soft drinks.
- Cook foods. Eat only thoroughly cooked foods, and eat them while they are still hot. Avoid eating food from street vendors.
- Peel foods. Eat only fruit or nuts with a thick intact skin or shell that is removed immediately before eating.
- Avoid raw foods. Do not eat raw foods such as oysters or ceviche. Avoid salads and raw vegetables. Do not use untreated ice cubes in otherwise safe drinks.
- Avoid polluted water. Do not swim or fish in polluted water.

Preventive measures following natural disasters include guaranteeing the purity of community drinking water, either by large-scale chlorination and boiling or by bringing in bottled or purified water from the outside. Other important preventive measures at the community level include provision for the safe disposal of human feces and good food hygiene.

Because cholera is one of the few infectious diseases that can be spread by human remains (through fecal matter leaking from corpses into the water supply), during natural disasters, emergency workers who handle human remains are at increased risk of infection. It is considered preferable to bury corpses rather than to cremate them, however, and to allow survivors time to conduct appropriate burial ceremonies or rituals. The remains should be disinfected prior to burial and buried at least 90 feet (30 m) from sources of drinking water.

A cholera vaccines exists that can be given to travelers and residents of areas where cholera is known to be active, but the vaccine is not highly effective. It provides only 25% to 50% immunity and then only for a period of about six months. The

WWW.BOOKBAZ.IR

vaccine is never given to infants under six months of age. As of 2014, the Centers for Disease Control and Prevention (CDC) did not recommend routine cholera **vaccination** for travelers. Residents of cholera-plagued areas should discuss the value of the vaccine with their doctor.

REVISED BY REBECCA J. FREY, PhD

Cholestasis

Definition

Cholestasis is a condition caused by rapidly developing (acute) or long-term (chronic) interruption in the excretion of bile (a digestive fluid that helps the body process fat). The term is taken from the Greek *chole*, bile, and *stasis*, standing still.

Description

Cholestasis is caused by obstruction within the liver (intrahepatic) or outside the liver (extrahepatic). The obstruction causes bile salts, the bile pigment bilirubin, and fats (lipids) to accumulate in the bloodstream instead of being eliminated normally.

Intrahepatic cholestasis is characterized by widespread blockage of small ducts or by disorders such as hepatitis that impair the body's ability to eliminate bile. Extrahepatic cholestasis can occur as a side effect of many medications. It can also occur as a complication of surgery, serious injury, tissue-destroying infection, or intravenous feeding. Extrahepatic cholestasis can be caused by conditions such as tumors and **gallstones** that block the flow of bile from the gallbladder to the first part of the small intestine (duodenum).

Pregnancy increases the sensitivity of the bile ducts to estrogen, and cholestasis often develops during the second and third trimesters of pregnancy. This condition is the second most common cause of **jaundice** during pregnancy, but generalized **itching** (pruritus gravidarum) is the only symptom most women experience. Cholestasis of pregnancy tends to run in families. Symptoms usually disappear within two to four weeks after the baby's birth but may reappear if the woman becomes pregnant again.

A similar condition affects some women who take birth control pills. Symptoms disappear after the woman stops using **oral contraceptives**. This condition does not lead to chronic **liver disease**. A woman who develops cholestasis from either of these causes (pregnancy or birth control hormones) has an increased risk of developing cholestasis from the other.

Benign familial recurrent cholestasis is a rare condition characterized by brief, repeated episodes of itching and jaundice. Symptoms often disappear. This condition does not cause **cirrhosis**.

Drug-induced cholestasis may be a complication of **chemotherapy** or other medications. The two major types of drug-induced cholestasis are direct toxic injury and reactions unique to an individual (idiosyncratic reactions). In direct toxic injury, the severity of symptoms parallels the amount of medication involved. This condition develops a short time after treatment begins, follows a predictable pattern, and usually causes liver damage.

Direct toxic reactions develop in 1% of all patients who take chlorpromazine (Thorazine), a tranquilizer and antinausea drug. Idiosyncratic reactions may occur at the onset of treatment or at a later time. Allergic responses are varied and are not related to the amount of medication being taken.

Newborns and infants are particularly susceptible to the development of cholestasis as a consequence of immaturity of the liver.

Causes and symptoms

Intrahepatic cholestasis is usually caused by hepatitis or by medications that can produce symptoms

resembling hepatitis. Phenothiazine-derivative drugs, including chlorpromazine, can cause sudden **fever** and inflammation. Symptoms usually disappear after use of the drug(s) is stopped. In rare cases, a condition resembling chronic biliary cirrhosis (a progressive disease characterized by destruction of small bile ducts) persists even after the medication is stopped. Some patients experience a similar reaction in response to tricyclic antidepressants (amitriptyline, imipramine), phenylbutazone (Butazolidin), erythromycin estolate (Estomycin, Purmycin), and other drugs. Intrahepatic cholestasis may also be caused by alcoholic liver disease, **primary biliary cirrhosis**, cancer that has spread (metastasized) from another part of the body, and a number of rare disorders.

Extrahepatic cholestasis is most often caused by a stone obstructing the passage through which bile travels from the gallbladder to the small intestine (common bile duct) or by pancreatic cancer. Less often, the condition occurs as a result of non-cancerous narrowing of the common duct (strictures), ductal carcinoma, or disorders of the pancreas.

Cholestasis caused by the use of **steroids** causes little, if any, inflammation. Symptoms develop gradually and usually disappear after the drug is discontinued. Other drugs that can cause cholestasis are:

- allopurinol (Zyloprim)
- amitriptyline (Elavil)
- azathioprine (Imuran)
- benoxaprofen (Oraflex)
- capotril (Capoten)
- carbamazepine (Tegretol)
- cimetidine (Tagamet)
- hydralazine hydrochloride (Apresoline Hydrochloride)
- imipramine (Tofranil)
- penicillin
- quinidine sulfate (Quinidex)
- ranitidine (Zantac)
- sulfonamides (Apo-Sulfatrim, sulfamethoxazole)
- sulindac (Clinoril, Saldac)

Symptoms of both intrahepatic and extrahepatic cholestasis include a yellow discoloration of the skin (jaundice), dark urine, and pale stools. Itching over the skin may be severe if the condition is advanced.

Symptoms of chronic cholestasis include:

- skin discoloration
- scars or skin injuries caused by scratching
- bone pain
- yellowish fat deposits beneath the surface of the skin (xanthoma) or around the eyes (xanthelasma)

Patients with advanced cholestasis feel ill, tire easily, and are often nauseated. Abdominal **pain** and such systemic symptoms as anorexia, **vomiting**, and fever are usually due to the underlying condition that causes cholestasis.

Diagnosis

Examination and tests

Determining whether obstruction exists inside or outside the liver is the essential part of diagnosis. A history of hepatitis or heavy drinking, recent use of certain drugs, and symptoms like **ascites** (abnormal abdominal swelling) and splenomegaly (enlarged spleen) suggest intrahepatic cholestasis. Pain or rigidity in the gallbladder or pancreas suggest an extrahepatic form.

Blood tests and **liver function tests** can reveal the pattern and extent of liver injury, indicate functional abnormalities, and establish the cause of the condition. Most misdiagnoses occur when physicians rely more on laboratory analysis than on detailed medical history and the results of a thorough **physical examination**. Blood tests that may be ordered include measurement of serum bilirubin, serum bile salts, serum **cholesterol**, serum lipoprotein-X, serum 5-nucleotidase, and serum gamma-glutamyl transferase levels. Fecal fat levels may also be elevated in cholestasis. Special attention should be paid to liver function tests including levels of alkaline phosphatase (ALP). ALP levels more than three times greater than normal indicate cholestasis.

Once the disease pattern has been established, **ultrasound** may be performed to determine whether obstruction of the large duct has caused widening of small ducts located close to it. **Computed tomography scans** (CT) and **magnetic resonance imaging** (MRI) can provide more detailed information about the source of the obstruction.

Procedures

If these imaging procedures do not provide the information a physician, internist, or gastroenterologist needs to make a diagnosis of cholestasis, one of these procedures may be performed:

- direct cholangiography, an x-ray map of the bile ducts, enhanced by the use of contrast dye
- percutaneous transhepatic cholangiography, used to identify obstructions that impede the flow of bile from the liver to the digestive system, takes x-ray

WWW.BOOKBAZ.IR

KEY TERMS

Bile—A bitter yellow-green substance produced by the liver. Bile breaks down fats in the small intestine so that they can be used by the body. It is stored in the gallbladder and passes from the gallbladder through the common bile duct to the top of the small intestine (duodenum) as needed to digest fat.

Biliary—Of bile or of the gallbladder and bile ducts that transport bile and make up the biliary system or tract.

Computed tomography scans (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Endoscopic retrograde cholangiopancreatography—A diagnostic procedure for mapping the pancreatic and common bile ducts. A flexible tube with a light transmitter (fiberoptics) is placed in the duct. A contrast dye is instilled directly into the duct and a series of x-ray images are taken.

Hepatic—Of the liver, from the Greek word *hepar*.

Liver function tests—Tests used to evaluate liver metabolism, storage, filtration, and excretion. The tests include alkaline phosphatase and serum alanine aminotransferase and aspartate aminotransferase.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Percutaneous transhepatic cholangiography—An x-ray examination of the bile ducts. A needle is passed through the skin (percutaneous) across or over the liver (transhepatic) and directly into a bile duct to inject a contrast dye. The dye enhances the x-ray image mapping the system of bile ducts (cholangiography).

Phenothiazine-derivative drugs—A large family of drugs derived from phenothiazine, a compound that in itself is too poisonous for human consumption. Phenothiazine derivatives include tranquilizers, medications that prevent vomiting, antihistamines, and drugs used to enhance the effectiveness of anesthesia.

Ultrasonography—A test using sound waves to measure blood flow. Gel is applied to a hand-held transducer that is pressed against the patient's body. Images are displayed on a monitor.

images of the bile ducts after a contrast dye has been injected by a needle passed directly into a hepatic duct

- endoscopic retrograde cholangiopancreatography (ERCP), which uses a special dye to outline the pancreatic and common bile ducts and highlight the position of any obstruction; a special tube with a light transmitter is inserted into the duct and a series of x-ray images is taken

A doctor who thinks a physical obstruction is responsible for progressive deterioration of a patient's condition may consider an exploratory surgical procedure (diagnostic laparotomy). **Liver biopsy** is sometimes performed if imaging tests do not indicate why a duct is enlarged, but results of a single biopsy may not represent the status of the entire organ.

Treatment

The goal of treatment is to eliminate or control the patient's symptoms. Discontinuing the use of certain drugs can restore normal liver function, but surgery may be needed to drain or remove obstructions or to widen affected ducts. A liver transplant may become necessary if complications occur.

Drugs

Rifampin (Rifadin, Rimactane), an antibacterial drug; Phenobarbital (Luminol), a barbiturate anticonvulsant that decreases serum bilirubin levels by increasing hepatic enzyme metabolims; and other drugs including urosodeoxycholic acid (Actigall, Urosol), and bile salt resins are sometimes prescribed to cleanse the system and eliminate bile salts and other toxic compounds.

Alternatives

Patients who have chronic cholestasis and have trouble digesting fat may have to restrict the amount of fat in their diet and take **calcium** and water-soluble vitamin supplements.

Prognosis

Symptoms almost always disappear after the underlying condition is controlled.

Some patients who have cholestasis experience symptoms only after infection develops, but chronic bile-duct obstruction always leads to cirrhosis. It may also cause **osteoporosis** (fragile bones) or osteomalacia (soft bones).

Emergency care is not required unless inflammation of the bile ducts (**cholangitis**) develops. Cancer should be considered when an adult suddenly develops cholestasis after the age of 50.

Cholesterol

Definition

Cholesterol is a waxy substance made by the liver and also acquired through diet. It is found in the blood and in all cells in the body. The body uses cholesterol to produce bile, some hormones, **vitamin D**, cell membranes, and myelin (the material that surrounds nerves). A high level of cholesterol in the blood is called **hypercholesterolemia**. High levels of blood cholesterol have been linked to **heart disease**.

Description

Cholesterol in small quantities is necessary for the body to function properly, but the liver is able to synthesize about 1,000 mg of cholesterol a day, which is all the body needs. However, because cholesterol is found in animal products—meat, fish, shellfish, egg yolks, and dairy products—people also get cholesterol through their diet, and too much cholesterol can be harmful.

Cholesterol does not dissolve in blood. Instead it moves through the circulatory system in combination with carrier substances called lipoproteins. There are two carrier-cholesterol combinations, low-density lipoprotein (LDL) or "bad" cholesterol and high-density lipoprotein or "good" cholesterol.

Most of the cholesterol in the body is LDL cholesterol. An excessive amount of LDL cholesterol is a major contributing factor to the development of heart disease. LDL picks up cholesterol in the liver and carries it through the circulatory system. When too much LDL cholesterol is present, it begins to drop out of the blood and stick to the walls of the arteries. The sticky material on artery walls is called plaque. (It is different from dental plaque that accumulates on teeth.) Plaque can reduce the amount of blood flowing through the arteries, and when bits of plaque break open, they can stimulate the formation of **blood clots**. If plaque or a blood clot block the coronary arteries that carry blood to the heart, **heart attack** (myocardial infarction) can occur. A **stroke** occurs if arteries carrying blood to the brain are blocked. In adults, a desirable LDL reading is less than 100 mg/dL.

High-density lipoprotein (HDL) or "good" cholesterol appears to carry excess LDL cholesterol

WWW.BOOKBAZ.IR

away from the walls of the arteries to the liver where it can be processed and removed from the body. High levels of HDL cholesterol are helpful; they seem to help protect the body from heart disease and heart attack. Low levels seem to increase the risk of heart disease. In adults, a desirable level of HDL is greater than 60 mg/dL.

A desirable total cholesterol level (LDL + HDL) is less than 200 mg/dL. According to the United States Centers for Disease Control and Prevention (CDC), the average total cholesterol level in American adults is 203 mg/dL, and 17% of Americans over age 20 have total cholesterol levels of 240 mg/dL or higher. This percentage has decreased from a high of 33% in 1960 as people have become more aware of the connection between high cholesterol levels and heart disease.

Specific risk factors include a high-fat, high-calorie diet, family history of high cholesterol, **obesity**, **alcoholism**, and lack of regular **exercise**. Because cholesterol also is produced naturally in the liver, overproduction may occur in even in people who limit their intake of high-cholesterol food. The chance of developing high cholesterol increases after the age of 45, and women are at higher risk of for developing high cholesterol levels than men. Both genetic inheritance and lifestyle factors affect cholesterol level.

Causes and symptoms

There are no readily apparent symptoms that indicate high LDL or low HDL cholesterol levels. The only way to determine cholesterol levels is through a simple blood test. According to the CDC, In 2014, about 71 million American adults (33.5%) have high LDL, or "bad" cholesterol; only one out of every three adults with high LDL cholesterol has the condition under control; less than half of adults with high LDL cholesterol get treatment; and people with high total cholesterol have approximately twice the risk of heart disease as people with optimal levels.

Diagnosis

High cholesterol often is diagnosed from blood tests that are part of a routine **physical examination**. The condition usually is treated by general practitioners or family practice physicians unless other conditions concerns complicate the patient's health status. Total cholesterol, LDL, HDL, and **triglycerides** (another type of blood fat that plays a role in heart disease) are measured by a blood test called a lipid panel. The cost of a lipid panel is moderate and routinely is covered by health insurance and HMO plans, including Medicare. Home cholesterol testing kits are sold over the counter (without prescription), but these test only for total cholesterol. The results of a home test should be used only as a guide, and if the total cholesterol level is high, a physician should perform a lipid panel. The generally recommended levels of LDL, HDL, and total cholesterol are listed in the previous table. However, physician recommendations for individuals may vary depending on the individual's risk factors such as **hypertension** (high blood pressure), a family history of heart disease, current heart disease, diabetes, age, alcoholism, and **smoking**.

Treatment

Treatment normally begins with lifestyle changes unless the individual already has heart disease and/or has high cholesterol and additional risk factors. In such situations drug therapy may begin at the same time lifestyle changes are implemented. Drug therapy is not a substitute for lifestyle changes; the two must be used together to effectively reduce blood cholesterol levels.

Lifestyle changes

The main lifestyle changes used to treat high cholesterol are diet, exercise, weight loss, and stopping smoking. The National Heart, Lung, and Blood Institute has developed a diet called the Therapeutic Lifestyle Changes (TLC) diet designed to help lower cholesterol and control weight. TLC diet recommendations include the following:

- Fewer than 7% of daily total calories should come from saturated fat.
- No more than 25–35% of total daily calories should come from any type of fat.
- Daily intake of cholesterol should be no more than 200 mg. (In 2007, the average American man ate 337 mg of cholesterol daily and the average woman ate 217 mg daily.)
- Daily sodium intake should be no more than 2,400 mg.
- Daily total calories should be limited to what will maintain or reduce weight.

In addition to reducing cholesterol and fat, increasing the amount of fiber in the diet helps lower total blood cholesterol. High-fiber foods include products made with whole wheat (e.g., pasta, bread), brown rice, lentils, dried beans, and raw vegetables (e.g., celery, carrots, apples, pears). In the United States, food labels are required to list in the **nutrition** information panel calories, calories from fat, total fat, saturated fat, *trans* fat, cholesterol, **sodium**, total

carbohydrates, dietary fiber, sugars, protein, **vitamin A**, vitamin C, **calcium**, and iron. In addition, the following words have specific legal meanings on food labels.

- Cholesterol-free: Less than 2 mg of cholesterol and 2 g of saturated fat per serving.
- Low cholesterol: no more than 20 mg of cholesterol and 2 grams of saturated fat per serving.
- Fat-free: less than 0.5 grams of fat per serving.
- Low fat: no more than 3 grams or less of fat per serving.
- Less fat: A minimum of 25% less fat than the comparison food.
- Light (fat): A minimum of 50% less fat than the comparison food.

A calculator that factors in height, weight, age, and activity level to determine an individualized daily calorie and fats level can be found at http://www.nhlbisupport.com/cgi-bin/chd1/step2intro.cgi.

A vegetarian or vegan diet also may be effective in lowering cholesterol, since most cholesterol comes from eating cholesterol-containing animal products, which are reduced (vegetarian) or eliminated (vegan) in these **diets**. Vegetarians typically get up to 100% more fiber and up to 50% less cholesterol from food than non-vegetarians. The vegetarian low-cholesterol diet consists of at least six servings of whole grain foods, three or more servings of green leafy vegetables, two to four servings of fruit, two to four servings of legumes, and one or two servings of non-fat dairy products daily.

Exercise also is an important part of lowering LDL cholesterol and raising HDL cholesterol. Ideally, exercise should consist of 20–30 minutes of vigorous aerobic exercise (e.g., fast walking, bicycling, jogging, roller skating, swimming, walking up stairs) at least three times a week. Nevertheless, any regular exercise is helpful, especially for overweight individuals. Individuals should not avoid exercising simply because they cannot meet the ideal exercise regimen. Instead, they should make gentle exercise a part of their regular daily routine, gradually working up to more vigorous, sustained exercising.

Drug therapy

A variety of drugs may be prescrived to reduce cholesterol levels. All of these drugs have side effects that may make them unsuitable for certain individuals. Cholesterol-lowering medications include:

- Statins. These are the most frequently prescribed cholesterol-lowering class of drugs. Statins are effective in lowering LDL (bad) cholesterol by slowing the production of cholesterol in the body. However, some statins have been shown to cause a rare type of serious muscle damage (rhabdomyolysis). Other research suggests that statins benefit only to those at high risk for heart attack and not people at low to moderate risk. Examples of statins include atorvastatin (Lipitor), fluvastatin (Lescol), lovastatin (Altocor, Mevacor), pravastatin (Pravachol), and simvastatin (Zocor).
- Bile acid sequestrants, also called resins. These drugs increase the amount of bile excreted in feces. This forces the liver to make more bile, and since cholesterol is used in making bile, more cholesterol is used and less enters the bloodstream, thus lowering cholesterol levels. Bile acid sequestrants are prescribed along with other cholesterol-lowering drugs such as statins. Examples include acid sequestrants include cholestyramine (Prevalite, Questran), colesevelam (Welchol), and colestipol (Colestid).
- Niacin (nicotinic acid.) A dietary supplement that should be used only under supervision of a physician. It helps to lower LDL cholesterol.
- Cholesterol absorption inhibitors. These drugs reduce the amount or cholesterol in food that is absorbed by the intestines. Examples include Ezetimibe (Zetia) and a combination of ezetimibe and the statin simvastatin (Vytorin).
- Fibrates also called fibric acid derivatives. These mainly lower triglycerides, but also may raise HDL (good) cholesterol. They rarely used alone to treat high cholesterol. Examples include gemfibrozil (Loprid), clofibrate (Atromid-S), and fenofibrate (Tricor).

Alternatives

Alternative practitioners also recommend diet and exercise as first-line treatment to lower high cholesterol levels. Some herbal supplements are also recommended by alternative practitioners to reduce cholesterol levels. Individuals using any herbal remedy or alternative therapy should discuss its use with a physician. Harmful interactions between herbal remedies and conventional medicines are possible. The following are some of the alternative therapies that have been investigated.

- Garlic. As of 2014, the National Center for Complementary and Alternative Medicine (NCCAM) reported several studies that have shown short term (up to 3 months) reduction in total blood cholesterol levels when garlic (standardized dehydrated tablets, aged garlic extract, oil macerates, distillates, raw garlic) was compared to placebo treatments, but

WWW.BOOKBAZ.IR

KEY TERMS

Dietary supplement—A product, such as a vitamin, mineral, herb, amino acid, or enzyme, that is intended to be consumed in addition to an individual's diet with the expectation that it will improve health.

Feces—The solid waste that is left after digestion. Feces form in the intestines and leave the body through the anus.

Fiber—Also known as roughage or bulk. Insoluble fiber moves through the digestive system almost undigested and gives bulk to stools. Soluble fiber dissolves in water and helps keep stools soft.

Hypertension—Abnormally high blood pressure in the arteries.

Placebo—A pill or liquid given during the study of a drug or dietary supplement that contains no medication or active ingredient. Usually study participants do not know if they are receiving a pill containing the drug or an identical-appearing placebo.

Triglycerides—A type of fat found in the blood. High levels of triglycerides can increase the risk of coronary artery disease.

these reductions were not found in longer (6 month) studies. Research is ongoing to clarify these results.

- Soy. According to NCCAM, research suggests that soy may slightly lower levels of LDL cholesterol.
- Green tea. Some alternative practitioners suggest that green tea can lower LDL cholesterol. NCCAM finds that there is not yet enough reliable data to evaluate this claim.
- Red clover, grape seed extract, flaxseed oil, blue-green algae. Although these may be recommended by alternative practitioners, there is little evidence that they affect cholesterol levels.
- Cholestin (red yeast rice). This dietary supplement is a processed form of red yeast fermented with rice. It is a remedy used for centuries in traditional Chinese medicine. Cholestin is not approved or regulated by the United States Food and Drug Administration (FDA). It may reduce LDL cholesterol and increase HDL cholesterol, but should not be taken in place of prescription cholesterol-lowering drugs. Before using, discuss this supplement cholestrin with a physician.

Prognosis

High cholesterol is a major risk factor for heart disease. Left untreated, too much LDL cholesterol may clog the blood vessels, leading to chest **pain** (**angina**), blood clots, and heart attacks. By reducing LDL and total cholesterol levels, people with heart disease may prevent further heart attacks and strokes, prolong and improve their quality of life, and slow or reverse cholesterol build up in the arteries. In people without heart disease, lowering cholesterol levels may decrease the risk of a first heart attack or stroke.

Prevention

The habit of eating a low-fat, low-cholesterol, high-fiber diet and regular exercise is the healthiest and least expensive way control cholesterol levels and reduce the risk of heart disease. Other preventative measures include not smoking, limiting alcohol consumption, and maintaining an optimal weight. In a small 2003 Canadian study, people who ate a low-fat vegetarian diet consisting of foods that are found to help lower cholesterol dropped their levels of LDL cholesterol as much as some individuals taking statin drugs. For people with high risk factors for heart disease or pre-existing heart disease, such as a family history of heart disease, diabetes, and being over the age of 45, cholesterol-lowering medication may be effective. However, as of 2014, there was some question about whether these drugs had a preventative effect in individuals with no pre-existing heart disease and low to moderate risk.

Cholesterol and triglyceride tests

Definition

Cholesterol and triglyceride tests are components of a lipid profile that measure the amounts of fatty substances in the blood and provide important data about an individual's risk for developing cardiovascular (heart) disease.

Purpose

The purpose of **cholesterol** and triglyceride tests is to evaluate an individual's risk of cardiovascular (heart) disease.

Description

The body uses cholesterol when building cells and producing hormones. An excess of certain types of cholesterol in the blood (termed LDL cholesterol, or low-density lipoprotein, and VLDL cholesterol, or very low-density lipoprotein) can build up along the inside of the artery walls, forming plaque. Large amounts of plaque increase the chances of having a **heart attack** or **stroke**. Another category of cholesterol, called HDL cholesterol or high-density cholesterol, may actually be protective against **heart disease**.

Triglycerides are a type of fat the body uses for storing energy. Only small amounts are found in the blood. Having a high triglyceride level along with a high LDL cholesterol may increase a person's risk of having heart disease more than having only a high LDL cholesterol level.

Cholesterol and triglyceride testing is done for several reasons, including:

- as a component of a routine physical examination to screen for a lipid disorder
- to evaluate an individual's risk for heart disease
- to evaluate an individual's response to drugs used to treat lipid disorders
- to check for a rare genetic disease that causes very high cholesterol levels in persons that have unusual symptoms such as yellow fatty deposits in the skin (xanthomas) or around the eyes (xanthelasma)

Cholesterol and triglyceride tests are components of a lipid profile. A lipid profile includes four blood tests: total cholesterol, HDL cholesterol, LDL cholesterol, and triglycerides.

Dietary fats, including cholesterol, are absorbed from the small intestine. They are converted into triglycerides, which are then packaged into lipoproteins. All of these products are transported into the liver by chylomicrons. After a fast (not eating) lasting at least 12 hours, chylomicrons are absent from the bloodstream. This is the reason why people who are having an LDL test must fast overnight.

Cholesterol and triglyceride tests are typically ordered by a family doctor, internist, or geriatrician. The blood sample is usually obtained by a nurse, phlebotomist, or medical technologist. Once the blood sample is tested or processed by a medical technologist, the results are usually reviewed and interpreted by the physician who initially ordered the lipid profile.

Cholesterol and triglyceride tests can be ordered at any time. Some medical experts recommend routine cholesterol and triglyceride testing to screen for problems that affect the way cholesterol is produced, used, carried in the blood, or disposed of by the body. Regular cholesterol testing may also be done to verify that an individual's diet, medication use, weight loss, and **exercise** efforts are having a positive effect on his or her overall risk of cardiac disease.

Preparation

Fasting for a minimum of 12 hours before drawing blood contributes to a more accurate measurement of cholesterol and triglycerides in the blood. At the time

WWW.BOOKBAZ.IR

of drawing blood, the only preparation needed is to clean the venipuncture site with alcohol.

Aftercare

Routine lipid profiles that are used to monitor the effectiveness of drugs intended to reduce serum cholesterol are usually performed every three months.

Results

Total cholesterol levels are categorized as follows:

- desirable: less than 200 mg/dL
- borderline high: 200–239 mg/dL
- high: 240 mg/dL or more

Low-density cholesterol levels are categorized as follows:

- optimal: less than 100 mg/dL
- near or above optimal: 100–129 mg/dL
- borderline high: 130–159 mg/dL
- high: 160–189 mg/dL
- very high: 190 mg/dL or more

High-density cholesterol levels are categorized as follows:

- major risk for cardiovascular disease: less than 40 mg/dL in men or less than 50 mg/dL in women
- protective against cardiac disease: 60 mg/dL and above

Triglyceride levels are classified as follows:

- normal: less than 150 mg/dL
- borderline high: 150–199 mg/dL
- high: 200–499 mg/dL
- very high: 500 mg/dL and higher

Pharmaceutical interventions are based, in part, on cholesterol and triglyceride test values. However, it is important to note that cholesterol and triglyceride levels vary according to a person's age and gender. In addition, ranges for cholesterol and triglyceride values vary slightly among different laboratories.

Risks

The most common risks of cholesterol or triglyceride tests are minor bleeding (hematoma) or bruising at the site of venipuncture.

Cholesterol-reducing drugs

Definition

Cholesterol-reducing drugs belong to a group of medicines that reduce the amount of **cholesterol** (a fat-like substance) in the blood.

Purpose

Drugs in this group are used as part of a comprehensive treatment program of cholesterol management that includes diet, physical activity, and weight control to reduce the risks of heart attacks and strokes.

Description

There are four classes of cholesterol lowering drugs: bile acid sequesterants, HMG-CoA inhibitors, fibric acid derivatives, and miscellaneous.

Examples of bile acid sequesterants include cholestyramine (Questran), colestipol (Colestid), and colesevalam (Welchol). These drugs act by binding with bile in the intestine to block the digestion of fats and increase the excretion of cholesterol in the stool.

HMG-CoA inhibitors are called statins. Examples include atorvastatin (Lipitor), cerivastatin (Baycol), fluvastatin (Lescol), lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), and rosuvastatin (Crestor). These drugs block a liver enzyme involved in producing cholesterol.

The class of fibric acid derivatives includes clofibrate (Atromid-S); gemfibrozil (Lopid); and fenofibrate (Tricor). These drugs may act by reducing the ability of the liver to make cholesterol.

Niacin, vitamin B_3, is a miscellaneous cholesterol reducing drug. It reduces the ability of the liver to make cholesterol. Exetimibe (Zetia) is also a miscellaneous drug. It acts by blocking the absorption of cholesterol from the intestine.

Sometimes drugs are combined together from more than one class.

Recommended dosage

The dose of drug depends on the type of drug used. The prescribing physician or the pharmacist who filled the prescription can advise about the correct dosage.

Precautions

Periodic blood tests are usually done to check cholesterol and liver enzyme levels.

Drugs in this group are part of a comprehensive treatment program for managing cholesterol and the risk of **heart attack** and **stroke**, including diet, physical activity and weight management.

People over 60 years of age may be more sensitive to the side/adverse effects of some cholesterol-reducing drugs.

Anyone taking statins should notify health care professionals before having surgery or receiving emergency treatment in order to reduce the risk of side/adverse effects from additional drugs used at those times.

ALLERGIES. Anyone who has had unusual reactions to cholesterol-reducing drugs in the past should inform prescribing physicians before taking the drugs again. Prescribers should be told about **allergies** to foods, dyes, preservatives or other substances.

PREGNANCY. Statins should not be taken by women who are pregnant as they may interfere with normal fetal development.

Bile sequesterants may interfere with the ability of pregnant women to absorb fat soluble **vitamins** necessary for normal fetal growth and development.

BREASTFEEDING. Because Questran, Welchol and Colestid interfere with the absorption of vitamins, women who use these drugs while **breastfeeding** should ask their physicians about taking vitamin supplements.

Women who are breastfeeding should talk to their physicians before using Lopid. Whether this drug passes into breast milk is not known. But because animal studies suggest that it may increase the risk of some types of cancer, women should carefully consider the safety of using it while breastfeeding.

Statins enter breast milk and should not be used by women who are breastfeeding their babies.

OTHER MEDICAL CONDITIONS. Cholesterol-reducing drugs may make some medical problems worse. Before using these drugs, people with any of these medical conditions should make sure their physicians are aware of their conditions:

- stomach or liver problems, including stomach ulcer
- constipation

WWW.BOOKBAZ.IR

- hemorrhoids
- gallstones or gallbladder disease
- bleeding problems
- underactive thyroid

People with kidney or **liver disease** may be more likely to have blood problems or other side effects when they take certain cholesterol-reducing drugs. Some drugs of this type may actually raise cholesterol levels in people with liver disease.

Patients with any of the following medical conditions may develop problems that could lead to kidney failure if they take statins:

- organ transplant anti rejection medications
- recent major surgery
- seizures (convulsions) that are not well controlled

People with **phenylketonuria** (PKU) should be aware that sugar-free formulations of some cholesterol-reducing drugs contain phenylalanine.

USE OF CERTAIN MEDICINES. Cholesterol-reducing drugs may change the effects of other medicines. Patients should not take any other medicine that has not been prescribed or approved by a physician who knows they are taking cholesterol-reducing drugs.

Risks

Lopid,Tricor, and Clofibrate

Adverse effects from these drugs include upset stomach, nausea, **vomiting** or **diarrhea**, **constipation**, **headache**, **fatigue**, **dizziness**, and skin rash.

Statins

Adverse effects from these drugs include headache; chest, back, and leg **pain**, cramps and weakness; swollen legs and feet; upset stomach, abdominal pain, and diarrhea or constipation.

Questran, Welchol, and Colestid

Adverse effects from these drugs include **heartburn**, upset stomach, nausea, vomiting, constipation, headache.

Zetia

Adverse effects from Zetia include fatigue and back and leg cramps, weakness and pain.

Niacin

Adverse effects from niacin include **palpitations**, irregular heart beat, flushed feeling of the skin, and dizziness.

Interactions

Lopid, Tricor, and Clofibrate

These drugs increase the blood thinning effects of warfarin (Coumadin).

These drugs increase the weakness and muscle damage, adverse effects, of statins. They should not be taken together.

Statins

Antifungal drugs, Diflucan, Sporanoz and Nizoral increase the adverse effects of statins on muscles.

Lopid, Triccor, and Clofibrate decrease the effectiveness of statins and increase the risk of adverse muscle effects.

The antiseizure medicine Tegretol reduces the effectiveness of statins.

Cyclosporine, used to prevent organ rejection, increases the effectiveness and risk of adverse muscle effects of statins.

Diltiazem (Cardizem) increases the effects and risks of adverse muscle effects of statins.

Grapefruit juice increases the effects and risks of adverse muscle effects of statins.

The erythromycin family of **antibiotics** increases the risks of adverse muscle effects of statins.

Antiretroviral drugs used to treat **AIDS** may increase the risks of adverse muscle effects of statins.

Drugs used to treat **tuberculosis** may reduce the effectiveness of statins

Verapamil (Calan) may increase the effects and risks of adverse muscle effects of statins

Questran, Welchol, and Colestid

These drugs decrease the effectiveness of cortisone drugs.

These drugs decrease the effectiveness of statins.

Taking some cholesterol-reducing drugs with blood thinners (anticoagulants) may increase the chance of bleeding.

Combining statins with gemfibrozil, cyclosporine (Sandimmune) or niacin may cause or worsen problems with the kidneys or muscles.

James Waun, MD, RPh

Cholinergic drugs

Definition

Cholinergic drugs are medications that mimic the effects of acetylcholine, the naturally occurring neurotransmitter, on the parasympathetic nervous system.

Purpose

Cholinergic drugs produce the same effects as acetylcholine by stimulating smooth muscle contractions in the intestinal tract and bladder, dilating blood vessels, constricting bronchioles (breathing tubes), increasing production of saliva, mucus, sweat, and tears, and constricting the pupils in the eyes.

Cholinergic blockers (described elsewhere) are drugs that indirectly produce similar effects as cholinergic drugs by inhibiting the action of the naturally occurring enzyme, acetylcholinesterase, that inactivates acetylcholine.

Some cholinergic drugs, including edrophonium (Tensilon), neostigmine (Prostigmine), and piridogstimina (Mestinon) are used to improve muscle function in diagnosing and treating **myasthenia gravis**, a disease causing skeletal muscular weakness.

Pilocarpine (Isopto, Salagen, Pilopine) is a cholinergic drug that is used as an eye drop to constrict the pupil of the eye(s) to help control **glaucoma**, a disease caused by increased pressure inside the eye. As a tablet, it is used to counteract **dry mouth** from x-Ray treatments for cancers of the head and neck.

Bethanachol (Urecholine) is a cholinergic drug used to treat non-obstructive urinary retention after surgery and in **neurogenic bladder**.

Description

These drugs are available as capsules, tablets, injections, and eye drops.

Recommended dosage

Physicians prescribe dosage of these drugs depending on the circumstances of individual cases.

Precautions

These drugs should not be used if there is obstruction or weakness in the muscles in the urinary or digestive tracts.

Cholinergic drugs may aggravate **asthma**, peptic ulcer disease, or slow heart beat.

KEY TERMS

Cholinergic nerves—Nerves that are stimulated by acetylcholine.

Glaucoma—A disease of the eye with increased pressure that can produce blindness.

Myasthenia gravis—A disease with progressive weakness of skeletal, voluntary muscles.

Parasympathetic nervous system—The part of the nervous system responsible for secretions, skeletal and smooth muscle tone, and slowing heart rate.

These drugs may aggravate **hyperthyroidism**, parkinsonism, **coronary artery disease**, or low blood pressure.

Risks

Possible adverse effects of cholinergic drugs include:

- slow heart beat and low blood pressure, possibly leading to cardiac arrest.
- flushing of the skin
- muscle cramps, and pain
- nausea, abdominal cramps, and pain
- headache, convulsions
- difficulty breathing
- increased stomach acid and saliva
- urinary urgency

Chondromalacia patellae

Definition

Chondromalacia patellae refers to the progressive erosion of the articular cartilage of the knee joint, that is the cartilage underlying the kneecap (patella) that articulates with the knee joint.

WWW.BOOKBAZ.IR

Description

Chondromalacia patellae (CMP), also known as patello-femoral **pain** syndrome or patello-femoral **stress** syndrome, is a syndrome that causes pain/discomfort at the front of the knee. It is associated with irritation or wear on the underside of the kneecap, or patella. In a normal knee, the articular cartilage is smooth and elastic and glides smoothly over the surface of the thighbone, or femur, when the knee is bent. Erosion of the cartilage roughens the surface and prevents this smooth action.

CMP is most common in adolescent females, although older people may also develop it. An average of two out of 10,000 people develop this condition, many of them runners or other athletes.

Causes and symptoms

CMP is the result of the normal **aging** process, overuse, injury, or uneven pressures exerted on the knee joint. In teens, CMP may be caused by uneven growth or uneven strength in the thigh muscles. Growth spurts, common in teens, may result in a mildly abnormal alignment of the patella, which increases the angle formed by the thigh and the patellar tendon (Q-angle). This condition adds to the damage. Symptoms include pain, normally around the kneecap, and a grinding sensation felt when extending the leg. The pain may radiate to the back of the knee, or it may be intermittent and brought on by squatting, kneeling, going up or down stairs, especially down, or by repeated bending of the joint.

Diagnosis

Diagnosis is established during a **physical examination** performed by a general practitioner or an orthopedist, and is based on frequency of symptoms and confirmed by x rays of the knee. The CMP erosion can also be seen on an MRI, although this type of scan is not routinely performed for this purpose. The patient should inform the doctor about any previous injuries to the joint.

Treatment

Initial treatment may consist of resting the knee using crutches, along with Tylenol or a non-steroidal anti-inflammatory drug (NSAID) such as Motrin for seven to 10 days. The person should limit sports activity until the joint is healed and may use ice followed by heat to decrease inflammation. When the doctor allows the patient to resume sports, a knee brace may be prescribed in the form of a stabilizer with a hole at the kneecap.

KEY TERMS

Arthroscopic knee surgery—Surgery performed to examine or repair tissues inside the knee joint through a special scope (arthroscope).

Femur—The thigh bone.

Isometric exercises—Exercises which strengthen through muscle resistance.

Osteoarthritis—Degenerative joint disease.

Quadriceps, hip flexors, hamstrings—Major muscles in the thigh area which affect knee mechanics.

Treatment also includes low impact exercises to strengthen the quadriceps muscles which help stabilize the knee joint. **Physical therapy** may be suggested at the start of this program so as to help the patient learn the correct method of performing the exercises.

Approximately 85% of people do well with conservative CMP treatment. The remainder still have severe pain and may require **arthroscopic surgery** to repair the tissues inside the knee joint. In more severe cases, open surgery may be required to realign the kneecap and perhaps other corrections.

Alternatives

Physical therapy offers treatments that may help CMP patients. Aqua therapy has the benefit of exercising the knee without putting stress on it and it also strengthens the thigh muscles. **Biofeedback** can be used to learn tensing and relaxing specific muscles to relieve pain. These techniques have the benefit of no side effects. **Massage therapy** might be beneficial as well. **Calcium**, **minerals**, and **vitamins** as part of a balanced diet will aid healing and help prevent further problems.

Prognosis

In most teens with CMP, the prognosis is excellent since the damage is reversible when treatment starts before the cartilage begins to break down. With proper treatment and preventive techniques, teenagers will complete their growth without permanent damage to the joint. Only about 15% of patients require surgical intervention. Older people may go on to develop **osteoarthritis** in the knee.

Prevention

Proper exercises are the best preventive measure. Since tightness of thigh muscles is a risk factor, warming up before athletic activities is recommended, as well as participating in a variety of sports rather than just one. Stretching exercises increase flexibility of the quadriceps, hip flexors, and hamstrings. Strengthening exercises such as short arc leg extensions, straight leg raises, quadriceps isometric exercises, and stationary bicycling are also recommended.

Choriocarcinoma

Definition

A choriocarcinoma is type of germ cell cancer containing trophoblast cells.

Demographics

Choriocarcinoma is a rare tumor type which, in women, develops in one out of every 40 hydatidiform **moles** and in one out of 20,000-40,0000 pregnancies in the United States. The incidence of choriocarcinoma is more prevalent in countries such as India (incidence rate of one in every 500-600 pregnancies), Mexico, Paraguay, and Sweden. African American women have the highest incidence rates of choriocarcinoma and have the lowest survival rates once diagnosed with this cancer. This type of cancer is 5-15 times more likely to be diagnosed in women over the age of 40 than in women under 40 years of age.

Choriocarcinoma that develops in men usually develops as a type of testicular tumor. Choriocarcinoma of the testes is a rare cancer in men. However, this tumor type, which is primarily diagnosed in younger men, is the most common cancer diagnosed in men between the ages of 15-35 years. This cancer affects white males more than males of other racial/ethnic groups.

Description

Choriocarcinomas are cancers that develop from germ cells, cells that ordinarily turn into sperm or eggs. Choriocarcinomas resemble the cells that surround an embryo in the uterus. Most of these cancers form inside the reproductive organs. Some originate in the testes or ovaries, especially in young adults. Others develop in the uterus after a **pregnancy** or miscarriage—particularly following the presence of a **hydatidiform mole**. A few choriocarcinomas arise in sites outside the reproductive organs.

Choriocarcinomas are one of the most dangerous germ cell cancers. They usually grow quickly and spread widely. Occasionally, this cancer grows so fast that the original tumor outgrows its blood supply and dies, leaving behind only a small scar.

Causes and symptoms

Choriocarcinomas result from genetic damage to a germ cell. Males with **Klinefelter syndrome** are especially likely to develop extragonadal **germ cell tumors**.

The symptoms of a choriocarcinoma vary, depending on where the tumor originates and where it spreads. In the uterus, the most common symptom is bleeding. Other symptoms associated with tumors that have metastasized include purple or blue/black nodules on the lower genital tract tissues, abdominal tenderness, and **jaundice** if the tumor has spread to the liver. Cancers in the ovary often have only subtle signs such as widening of the waistline or **pain**.

In the testes, choriocarcinomas can often be felt as small painless lumps.

Choriocarcinomas that spread to other organs may reveal their presence by bleeding. In the brain, this bleeding can cause a **stroke**.

Diagnosis

Examination

Choriocarcinomas are usually referred to an oncologist, a doctor who specializes in cancer treatment. To diagnose this tumor, the doctor will do a **physical examination** and examine the internal organs with x rays or **ultrasound** studies.

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—A sample of an organ taken to look for abnormalities. Also, the technique used to take such samples.

Chemotherapy—The treatment of cancer with drugs.

Computed tomography (CT) scan—A special x-ray technique that produces a cross sectional image of the organs inside the body.

Extragonadal—In a location other than the reproductive organs.

Germ cell—One of the cells that ordinarily develops into eggs or sperm (also sperm and eggs).

Gonads—The ovaries or testes.

Hydatidiform mole—Also called a molar pregnancy. A mass of abnormal, partially developed tissues inside the uterus (womb). Moles develop during a pregnancy that begins with an abnormal fertilization. The mass may or may not be cancerous.

Klinefelter syndrome—A condition caused by extra X chromosome(s) in a male, that results in small testes and infertility together with increased height, decreased facial hair, and sometimes breast enlargement.

Magnetic resonance imaging—A type of study that uses changes induced by magnets to see cells and tissues inside the body.

Ovaries—The female sex organs that make eggs and female hormones.

Remission—The disappearance of the symptoms of cancer, although all of the cancer cells may not be gone.

Reproductive organs—The group of organs (including the testes, ovaries, and uterus) whose purpose is to produce a new individual and continue the species.

Testes—The male sex organs that make sperm and male hormones.

Testicular cancer—A cancer that originates in the testes.

Trophoblast—The tissues that surround an embryo and attach it to the uterus.

Tumor—A lump made up of abnormal cells.

Uterus—The organ where a child develops (womb).

Tests

Spreading of the cancer is detected with x rays, ultrasound studies, computed tomography (CT), or **magnetic resonance imaging** (MRI) scans.

Most choriocarcinomas make human chorionic gonadotropin (beta-hCG), a hormone normally found only during pregnancy. The presence of hCG in the blood can help diagnose this cancer and monitor the success of treatment.

Procedures

Choriocarcinomas are not always biopsied before being treated, because they tend to bleed heavily.

Treatment

Women diagnosed with choriocarcinomas that have not metastasized or who are diagnosed with tumors that are of low risk for metastasis are usually treated with the **chemotherapy** agent methotrexate. Another chemotherapy drug, actinomycin D, may be used if the patient has been diagnosed with liver dysfunction. Beta-hCG levels are monitored to determine response to therapy.

Women diagnosed with metastatic disease are divided into two groups based on whether or not they are at high risk for treatment failure. Patients who are at lower risk are treated with methotrexate or actinomycin and are typically cured with chemotherapy. Women deemed to be at higher risk are treated with combination chemotherapy. Patients with metastasis to the brain also receive whole brain **radiation therapy**. Other patients with brain involvement may be treated with stereotactic radiotherapy. A **hysterectomy** may be required for women who experience vaginal bleeding that cannot be controlled by nonsurgical means.

Currently, there is no consensus as to the best treatment for testicular choriocarinomas. Some chemotherapy agents that may be used include a combination of the drugs bleomycin, etoposide, and cisplatin for four cycles and/or the drugs vinblastine and ifosfamide. However, most choriocarcinomas of the testicles respond poorly to chemotherapy.

Surgery is typically recommended to remove a testicle (or both testicles if cancer has been detected in both) utilizing a surgical procedure termed radical inguinal orchiectomy.

Prognosis

The prognosis for choriocarcinomas in the uterus is very good. Although these tumors often spread throughout the body, chemotherapy results in a cure or remission in 75–100% of cases. The probability of a recurrence of choriocarcinoma in women who have been in remission with normal beta-hCG levels for at least one year is very small, typically less than 1%. Women who have had choriocarcinomas often go on to have normal pregnancies and deliveries.

Choriocarcinomas in other sites have a poorer prognosis. These tumors tend to spread quickly and do not respond well to chemotherapy. Although treatment can be effective, the outcome depends on how widely the cancer has metastasized. The prognosis is worse if the cancer can be found in the liver or brain, if hCG levels are high, or if the original tumor developed outside the gonads.

Choriocarcinomas of the testes metastasize early and typically do not respond to chemotherapy or radiation therapy. These cancers have a dismal prognosis with high mortality rates despite aggressive treatment.

Prevention

There is no known means of prevention. Early detection of the symptoms and prompt medical treatment can improve the odds of survival.

Chorionic gonadotropin test *see* **Human chorionic gonadotropin pregnancy test**

Chorionic villus sampling

Definition

Chorionic villus sampling (CVS), also known as chorionic villus biopsy, is a prenatal test that can detect genetic and chromosomal abnormalities of a fetus.

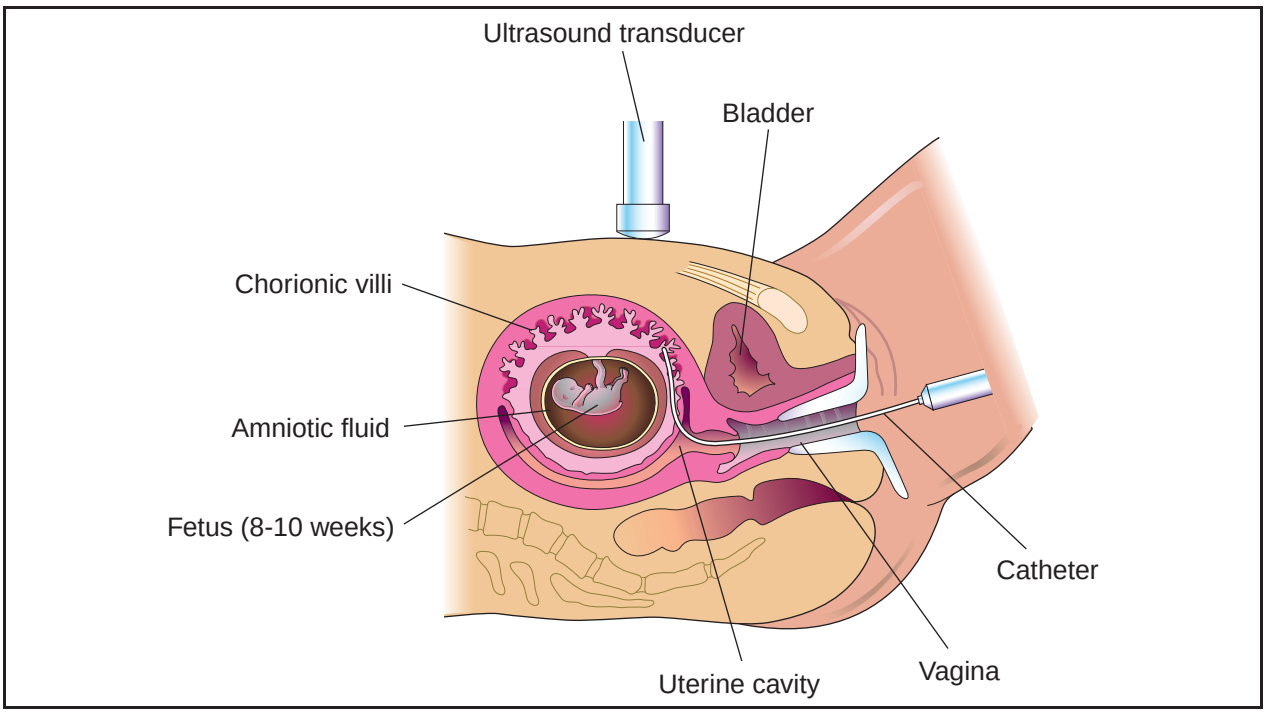
Purpose

Chorionic villus sampling is performed on pregnant women who are at risk for carrying a fetus with a genetic or chromosomal defect. Although it carries a slightly higher risk, CVS may be used in place of **amniocentesis** for women who have one or more of the following risk factors:

- women age 35 and older. The chance of having a child with Down syndrome increases with maternal age. For instance, the chance of having a baby with Down syndrome is one in 378 for a 35-year-old woman and increases to one in 30 for a 45-year-old woman.
- a history of miscarriages or children born with birth defects.
- a family history of genetic disease. Prenatal genetic testing is recommended if either the mother or father of the unborn baby has a family history of genetic disease or is known to be a carrier of a genetic disease.

Analysis of the cells from the chorionic villus enables the detection of over 200 diseases and disorders such as **Down syndrome**, **Tay-Sachs disease**, and **cystic fibrosis**. Gross rearrangements of the chromosomes and chromosome additions or losses are detected.

WWW.BOOKBAZ.IR



Chorionic villus sampling is performed on pregnant women who are at risk for carrying a fetus with a genetic or chromosomal defect. This procedure can be performed through the vagina and the cervix (transcervically) or through the abdomen (transabdominally). In the transcervical procedure, as depicted above, the physician uses ultrasound to help guide a catheter through the cervix into the uterus. By applying suction from the syringe attached to the other end of the catheter, a small sample of the chorionic villi is obtained. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

Chorionic villus sampling has been in use since the 1980s. This prenatal testing procedure involves taking a sample of the chorion frondosum—that part of the chorionic membrane containing the villi—for laboratory analysis. The chorionic membrane is the outer sac that surrounds the developing fetus. Chorionic villi are microscopic, finger-like projections that emerge from the chorionic membrane and eventually form the placenta. The cells that make up the chorionic villi are of fetal origin so laboratory analysis can identify any genetic, chromosomal, or biochemical diseases of the fetus.

Chorionic villus sampling is best performed between 10 and 12 weeks of **pregnancy**. The procedure is performed either through the vagina and the cervix (transcervically) or through the abdomen (transabdominally) depending upon the preferences of the patient or the doctor. In some cases, the location of the placenta dictates which method the doctor uses. Both methods are equally safe and effective. Following the preparation time, both procedures take only about five minutes. Women undergoing chorionic villus sampling may experience no **pain** at all or feel cramping or pinching. Occasionally, a second sampling procedure must be performed if insufficient villus material was obtained.

For the transcervical procedure, the woman lies on an examining table on her back with her feet in stirrups. The woman's vaginal area is thoroughly cleansed with an antiseptic, a sterile speculum is inserted into her vagina and opened, and the cervix is cleansed with an antiseptic. Using **ultrasound** as a guide, the doctor inserts a thin, plastic tube called a catheter through the cervix and into the uterus. The passage of the catheter through the cervix may cause cramping. The doctor carefully watches the image produced by the ultrasound and advances the catheter to the chorionic villi. By applying suction from the syringe attached to the other end of the catheter, a small sample of the chorionic villi are obtained. A cramping or pinching feeling may be felt as the sample is being taken. The catheter is then easily withdrawn.

For the transabdominal method, the woman lies on her back on an examining table. Ultrasound

KEY TERMS

Chorionic villi—Microscopic, finger-like projections that emerge from the outer sac which surrounds the developing baby. Chorionic villi are of fetal origin and eventually form the placenta.

Chromosomes—Human cells carry DNA in tightly compressed rod-like structures called chromosomes. Humans have 23 pairs of chromosomes including the sex chromosomes.

Down syndrome—A chromosomal disorder caused by an extra copy or a rearrangement of chromosome 21. Children with Down syndrome have varying degrees of intellectual disability (ID) and may have heart defects.

Fetus—Term for an unborn baby after the eighth week of pregnancy. Prior to seven weeks, it is called an embryo.

Rh sensitization—A woman with a negative blood type (Rh negative) who has produced antibodies against her fetus with a positive blood type (Rh positive). The mother's body considered the fetal blood cells a foreign object and mounted an immune attack on it.

Ultrasound—A safe, painless procedure which uses sound waves to visualize internal organs. A wand that transmits and receives the sound waves is moved over the woman's abdomen and internal organs can be seen on a video screen.

enables the doctor to locate the placenta. The specific area on the woman's abdomen is cleansed thoroughly with an antiseptic and a local anesthetic may be injected to numb the area. With ultrasound guidance, a long needle is inserted through the woman's abdominal wall, through the uterine wall and to the chorionic villi. The sample is obtained by applying suction from the syringe.

The chorionic villus sample is immediately placed into nutrient medium and sent to the laboratory. At the laboratory, the sample is examined under the microscope and any contaminating cells or material is carefully removed. The villi can be analyzed immediately, or incubated for a day or more to allow for cell division. The cells are stopped in the midst of cell division and spread onto a microscope slide. Cells with clearly separated chromosomes are photographed so that the type and number of chromosomes can be analyzed. Chromosomes are strings of DNA that have been tightly compressed. Humans have 23 pairs of chromosomes including the sex chromosomes. Rearrangements of the chromosomes or the presence of additional or fewer chromosomes can be identified by examination of the photograph. Down syndrome, for instance, is caused by an extra copy of chromosome 21. In addition to the chromosomal analysis, specialized tests can be performed as needed to look for specific diseases such as Tay-Sachs disease. Depending upon which tests are performed, results may be available as early as two days or up to eight days after the procedure.

Alternate procedures

There are alternate procedures for diagnosing genetic and chromosomal disorders of the fetus. Amniocentesis is commonly used and involves inserting a needle through the pregnant woman's abdomen to obtain a sample of amniotic fluid. Amniocentesis is usually performed in the second trimester at approximately 16 weeks gestation and the laboratory analysis may take two to three weeks. The two advantages of chorionic villus sampling are that it is performed during the first trimester and the results are available in about one week. The risk of **miscarriage** after amniocentesis is 0.5–1% (one to two women out of 200) which is lower than that for chorionic villus sampling (1–3%).

A noninvasive alternative is the maternal blood test called triple marker screening or multiple marker screening. A sample of the pregnant woman's blood is analyzed for three different markers: alphafetoprotein (AFP), human chorionic gonadotropin, and unconjugated estriol. The levels of these three markers in the mother's blood can identify unborn babies who are at risk for certain genetic or chromosomal defects. This screening test determines the chance that the fetus has the defect, but it cannot diagnose specific defects. A negative test result does not necessarily mean the unborn baby does not have a birth defect. For instance, this screening test can only predict 60–70% of the fetuses with Down syndrome. Pregnant women who have a positive triple marker screen are encouraged to undergo a diagnostic test, such as amniocentesis (by the time an AFP is done, it is too late to perform a CVS).

Results

Chorionic villi sampling allows parents of fetuses found to have a genetic defect to determine at an early

WWW.BOOKBAZ.IR

stage whether to continue or terminate the pregnancy. Should the decision be made to continue the pregnancy, parents will have time to prepare, both physically and psychologically, for parenting a child with disabilities related to a genetic defect.

Precautions

Chorionic villus sampling is not recommended for women who have vaginal bleeding or spotting during the pregnancy. It is not typically recommended for women who have Rh sensitization from a previous pregnancy.

Preparation

Prior to the chorionic villus sampling procedure the woman needs to drink fluids and refrain from urinating to ensure her bladder is full. These preparations create a better ultrasound picture.

Aftercare

It is generally recommended that women undergoing chorionic villus sampling have someone drive them home and have no plans for the rest of the day. Women with Rh negative blood must receive a Rho (D) immune globulin injection following the procedure. Women should call their doctor if they experience excessive bleeding, vaginal discharge, **fever**, or abdominal pain after the procedure.

Risks

Of women who undergo transcervical chorionic villus sampling, one third experience minimal vaginal spotting and 7–10% experience vaginal bleeding. One out of five women experience cramping following the procedure. Two to three women out of 100 (or 2–3%) will miscarry following chorionic villus sampling. The risk of infection is very low. Rupture of the amniotic membranes is a rare complication. Women with Rh negative blood may be at an increased risk for developing Rh incompatibility following chorionic villus sampling.

There have been reports of limb defects in babies following chorionic villus sampling. However, in 1996 the World Health Organization reported that the incidence of babies born with limb defects from 138,966 women who had undergone chorionic villus sampling was the same as for women who had not. Therefore, this study found no connection between chorionic villus sampling and limb defects.

Chronic fatigue syndrome

Definition

Chronic **fatigue** syndrome (CFS) is a condition that causes extreme tiredness. People with CFS have debilitating fatigue that lasts for six months or longer. They also have many other symptoms. Some of these are **pain** in the joints and muscles, **headache**, and **sore throat**. CFS does not have a known cause, but appears to result from a combination of factors.

Description

CFS is the most common name for this disorder, but it also has been called chronic fatigue and immune disorder (CFIDS), myalgic encephalomyelitis, low natural killer cell disease, post-viral syndrome, Epstein-Barr disease, and Yuppie flu. CFS has so many names because researchers have been unable to find out exactly what causes it and because there are many similar, overlapping conditions. Reports of a CFS-like syndrome called neurasthenia date back to 1869. Later, people with similar symptoms were said to have **fibromyalgia** because one of the main symptoms is myalgia, or muscle pain. Because of the similarity of symptoms, fibromyalgia and CFS are considered to be overlapping syndromes.

In the early to mid-1980s, there were outbreaks of CFS in some areas of the United States. Doctors found that many people with CFS had high levels of antibodies to the **Epstein-Barr virus** (EBV), which causes mononucleosis, in their blood. For a while they thought they had found the culprit, but it turned out that many healthy people also had high EBV antibodies. Scientists have also found high levels of other viral antibodies in the blood of people with CFS. These findings have led many scientists to believe that a virus or combination of viruses may trigger CFS.

CFS was sometimes referred to as Yuppie flu because it seemed to often affect young, middle-class professionals. In fact, CFS can affect people of any gender, age, race, or socioeconomic group. Although anyone can get CFS, most patients diagnosed with CFS are 25–45 years old, and about 80% of cases are in women. Estimates of how many people are afflicted with CFS vary due to the similarity of CFS symptoms to other diseases and the difficulty in identifying it. The Centers for Disease Control and Prevention (CDC) has estimated that four to 10 people per 100,000 in the United States have CFS. According to the CFIDS Foundation, about 500,000 adults in the United States (0.3% of the population) have CFS. This probably is a low estimate since these figures do not include children and are based on the CDC definition of CFS, which is very strict for research purposes.

Causes and symptoms

There is no single known cause for CFS. Studies have pointed to several different conditions that might be responsible. These include:

- viral infections
- chemical toxins
- allergies
- immune abnormalities
- psychological disorders

Although the cause is still controversial, many doctors and researchers now think that CFS may not be a single illness. Instead, they think CFS may be a group of symptoms caused by several conditions. One theory is that a microorganism, such as a virus, or a chemical injures the body and damages the immune system, allowing dormant viruses to become active. About 90% of all people have a virus in the herpes family dormant (not actively growing or reproducing) in their bodies since childhood. When these viruses start growing again, the immune system may overreact and produce chemicals called cytokines that can cause flu-like symptoms. Immune abnormalities have been found in studies of people with CFS, although the same abnormalities are also found in people with **allergies**, autoimmune diseases, cancer, and other disorders.

The role of psychological problems in CFS is very controversial. Because many people with CFS are diagnosed with depression and other psychiatric disorders, some experts conclude that the symptoms of CFS are psychological. However, many people with CFS did not have psychological disorders before getting the illness. Many doctors think that patients become depressed or anxious because of the effects of the symptoms of their CFS. One recent study concluded that depression was the result of CFS and was not its cause.

Having CFS is not just a matter of being tired. People with CFS have severe fatigue that keeps them from performing their normal daily activities. They find it difficult or impossible to work, attend school, or even to take part in social activities. They may have sleep disturbances that keep them from getting enough rest or they may sleep too much. Many people with CFS feel just as tired after a full night's sleep as before they went to bed. When they **exercise** or try to be active in spite of their fatigue, people with CFS experience what some patients call "payback"–debilitating exhaustion that can confine them to bed for days.

Other symptoms of CFS include:

- muscle pain (myalgia)
- joint pain (arthralgia)
- sore throat
- headache
- fever and chills
- tender lymph nodes
- trouble concentrating

WWW.BOOKBAZ.IR

• memory loss

A recent study at Johns Hopkins University found an abnormality in blood pressure regulation in 22 of 23 patients with CFS. This abnormality, called neurally mediated **hypotension**, causes a sudden drop in blood pressure when a person has been standing, exercising, or exposed to heat for a while. When this occurs, patients feel lightheaded and may faint. They often are exhausted for hours to days after one of these episodes. When treated with salt and medications to stabilize blood pressure, many patients in the study had marked improvements in their CFS symptoms.

Diagnosis

CFS is diagnosed by evaluating symptoms and eliminating other causes of fatigue. Doctors carefully question patients about their symptoms, any other illnesses they have had, and medications they are taking. They also conduct a **physical examination**, neurological examination, and laboratory tests to identify any underlying disorders or other diseases that cause fatigue. In the United States, many doctors use the CDC case definition to determine if a patient has CFS.

To be diagnosed with CFS, patients must meet both of the following criteria:

- Unexplained continuing or recurring chronic fatigue for at least six months that is of new or definite onset, is not the result of ongoing exertion, and is not mainly relieved by rest, and causes occupational, educational, social, or personal activities to be greatly reduced.
- Four or more of the following symptoms: loss of short-term memory or ability to concentrate; sore throat; tender lymph nodes; muscle pain; multi-joint pain without swelling or redness; headaches of a new type, pattern, or severity; unrefreshing sleep; and post-exertional malaise (a vague feeling of discomfort or tiredness following exercise or other physical or mental activity) lasting more than 24 hours. These symptoms must have continued or recurred during six or more consecutive months of illness and must not have started before the fatigue began.

Treatment

There is no cure for CFS, but many treatments are available to help relieve the symptoms. Treatments usually are individualized to each person's particular symptoms and needs. The first treatment most doctors recommend is a combination of rest, exercise, and a balanced diet. Prioritizing activities, avoiding overexertion, and resting when needed are key to maintaining existing energy reserves. A program of moderate exercise helps to keep patients from losing physical conditioning, but too much exercise can worsen fatigue and other CFS symptoms. Counseling and **stress reduction** techniques also may help some people with CFS.

Many medications, **nutritional supplements**, and herbal preparations have been used to treat CFS. While many of these are unproven, others seem to provide some people with relief. People with CFS should discuss their treatment plan with their doctors, and carefully weigh the benefits and risks of each therapy before making a decision.

Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen and naproxen, may be used to relieve pain and reduce **fever**. Another medication that is prescribed to relieve pain and **muscle spasms** is cyclobenzaprine (sold as Flexeril).

Many doctors prescribe low dosages of antidepressants for their sedative effects and to relieve symptoms of depression. **Antianxiety drugs**, such as **benzodiazepines** or buspirone may be prescribed for excessive **anxiety** that has lasted for at least six months.

Other medications that have been tested or are being tested for treatment of CFS are:

- Fludrocortisone (Florinef), a synthetic steroid, which is currently being tested for treatment of people with CFS. It causes the body to retain salt, thereby increasing blood pressure. It has helped some people with CFS who have neurally mediated hypotension.
- Beta-adrenergic blocking drugs, often prescribed for high blood pressure. Such drugs, including atenolol (Tenoretic, Tenormin) and propranolol (Inderal), are sometimes prescribed for neurally mediated hypotension.
- Gamma globulin, which contains human antibodies to a variety of organisms that cause infection. It has been used experimentally to boost immune function in people with CFS.
- Ampligen, a drug which stimulates the immune system and has antiviral activity. In one small study, ampligen improved mental function in people with CFS.

Alternatives

A variety of nutritional supplements are used for treatment of CFS. Among these are vitamin C, vitamin B_{12}, **vitamin A**, **vitamin E**, and various dietary **minerals**. These supplements may help improve immune and mental functions. Several herbs have been shown to

KEY TERMS

Arthralgia—Joint pain.

Cytokines—Proteins produced by certain types of lymphocytes. They are important controllers of immune functions.

Depression—A psychological condition, with feelings of sadness, sleep disturbance, fatigue, and inability to concentrate.

Epstein-Barr virus (EBV)—A virus in the herpes family that causes mononucleosis.

Fibromyalgia—A disorder closely related to CFS. Symptoms include pain, tenderness, and muscle stiffness.

Lymph node—Small immune organs containing lymphocytes. They are found in the neck, armpits, groin, and other locations in the body.

Lymphocytes—White blood cells that are responsible for the actions of the immune system.

Mononucleosis—A flu-like illness caused by the Epstein-Barr virus.

Myalgia—Muscle pain.

Myalgic encephalomyelitis—An older name for chronic fatigue syndrome; encephalomyelitis refers to inflammation of the brain and spinal cord.

Natural killer (NK) cell—A lymphocyte that acts as a primary immune defense against infection.

Neurally mediated hypotension—A rapid fall in blood pressure that causes dizziness, blurred vision, and fainting, and is often followed by prolonged fatigue.

Neurasthenia—A disorder with symptoms of irritability and weakness, commonly diagnosed in the late 1800s.

improve immune function and have other beneficial effects. Some that are used for CFS are astragalus (*Astragalus membranaceus*), **echinacea** (*Echinacea* spp.), garlic (*Allium sativum*), **ginseng** (*Panax ginseng*), gingko (*Gingko biloba*), evening primrose oil (*Oenothera biennis*), shiitake mushroom extract (*Lentinus edodes*), borage seed oil, and quercetin.

Many people have enhanced their healing process for CFS with the use of a treatment program inclusive of one or more alternative therapies. **Stress** reduction techniques such as **biofeedback**, **meditation**, **acupuncture**, and **yoga** may help people with sleep disturbances relax and get more rest. They also help some people reduce depression and anxiety caused by CFS.

Prognosis

The course of CFS varies widely for different people. Some people get progressively worse over time, while others gradually improve. Some individuals have periods of illness that alternate with periods of good health. While many people with CFS never fully regain their health, they find relief from symptoms and adapt to the demands of the disorder by carefully following a treatment plan combining adequate rest, **nutrition**, exercise, and other therapies.

Prevention

Because the cause of CFS is not known, there currently are no recommendations for preventing the disorder.

Toni Rizzo

Chronic granulomatous disease

Definition

Chronic granulomatous disease (CGD) is an inherited disorder in which white blood cells lose their ability to destroy certain bacteria and fungi.

WWW.BOOKBAZ.IR

Description

CGD is an X-linked genetic disease, meaning the defective gene is carried on the X chromosome (one of the sex chromosomes). Females have two copies of the X chromosome, whereas males have one X and one Y. CGD also is a recessive defect meaning that both copies of the chromosome must have the defect before it can be expressed. Females who have one X chromosome without the defect do not get this disease. Males, since they only have one X chromosome, get the disease if the defect is present. Thus, CGD affects mostly males.

CGD is an **immunodeficiency** disorder. Patients with immunodeficiency disorders suffer frequent infections. This happens because part of their immune system isn't working properly and the infectious microorganisms are not killed as rapidly as is normal. In CGD there is a defect in the ability of the white blood cells to kill bacteria and fungi. The white blood cells affected are phagocytic cells. They are part of the non-specific immune system and move via the blood to all parts of the body where they ingest and destroy microbes. Phagocytic cells are the first line of defense against microorganisms. In this disease, the decreased ability to kill microbes that they have ingested leads to a failure to effectively combat infectious diseases. Patients with CGD are subject to certain types of recurring infection, especially those of the skin, lungs, mouth, nose, intestines, and lymph nodes. With the exception of the lymph nodes, all of these areas are considered external tissues that come into contact with microorganisms from the environment. The lymph system drains all areas of the body to eliminate destroyed microorganisms and to assist the immune system in attacking microorganisms. Infections occur in the lymph nodes as a consequence of the normal draining function.

Causes and symptoms

The genetic defect that causes CGD reduces the amount of hydrogen peroxide and superoxide that white blood cells can make. These chemicals are important for killing bacteria and fungi. Without them the white blood cells ingest the microorganisms, but cannot kill them. In some cases, the microbes then replicate inside the white blood cell eventually causing its death.

Symptoms of the disease usually appear by age two. Frequent, recurrent infections of the skin, lungs (e.g. **pneumonia**), mouth (e.g. gingivitis), nose, intestines and lymph nodes are a hallmark of this disease. Patients may also develop multiple, recurrent liver abscesses and bone infections (**osteomyelitis**).

KEY TERMS

Immunodeficiency—A weakening of the body's immune system.

Phagocytic cells—A cell that ingests microorganisms and foreign particles.

Diagnosis

Diagnosis is made based on the observation of a pattern of recurrent infections. Blood tests of lymphocyte and antibody functions will be normal. Tests of phagocytic cells will show normal ingestion, but a greatly decreased ability to kill bacteria.

Treatment

Early, aggressive treatment of all infections is critical to the successful management of CGD. Patients are treated with **antibiotics** and immune serum. Antibiotics are used at the first sign of infection. Immune serum is a source of antibodies that help fight infections. Interferon gamma is an experimental treatment for CGD that has shown promising results. There is no cure for the underlying cause of chronic granulomatous disease

Prognosis

Although antibiotics can treat most infections and may help prevent others, premature death may result, typically due to repeated lung infections.

Prevention

Since CGD is a hereditary disorder, it cannot currently be prevented. Patients and their families may benefit from **genetic counseling**. Preventive (prophylactic) antibiotics may help keep some infections from occurring, and good hygiene, especially rigorous skin and mouth care, can help prevent infections in these areas. Avoiding crowds or other people who have infections are also effective preventive measures.

John T. Lohr, PhD

Chronic kidney failure

Definition

Chronic kidney failure occurs when disease or disorder damages the kidneys so that they are no longer capable of adequately removing fluids and wastes from the body or of maintaining the proper level of certain kidney-regulated chemicals in the bloodstream.

Description

Chronic kidney failure, also known as chronic renal failure, affects over 250,000 Americans annually. It is caused by a number of diseases and inherited disorders, but the progression of chronic kidney failure is always the same. The kidneys, which serve as the body's natural filtration system, gradually lose their ability to remove fluids and waste products (urea) from the bloodstream. They also fail to regulate certain chemicals in the bloodstream, and deposit protein into the urine. Chronic kidney failure is irreversible, and will eventually lead to total kidney failure, also known as end-stage renal disease (ESRD). Without proper treatment intervention to remove wastes and fluids from the bloodstream, ESRD is fatal.

Causes and symptoms

Kidney failure is triggered by disease or a hereditary disorder in the kidneys. Both kidneys are typically affected. The four most common causes of chronic kidney failure include:

- Diabetes. Diabetes mellitus (DM), both insulin dependant (IDDM) and non-insulin dependant (NIDDM), occurs when the body cannot produce and/or use insulin, the hormone necessary for the body to process glucose. Long-term diabetes may cause the glomeruli, the filtering units located in the nephrons of the kidneys, to gradually lose functioning.
- Glomerulonephritis. Glomerulonephritis is a chronic inflammation of the glomeruli, or filtering units of the kidney. Certain types of glomerulonephritis are treatable, and may only cause a temporary disruption of kidney functioning.
- Hypertension. High blood pressure is unique in that it is both a cause and a major symptom of kidney failure. The kidneys can become stressed and ultimately sustain permanent damage from blood pushing through them at an excessive level of pressure over a long period of time.
- Polycystic kidney disease. Polycystic kidney disease is an inherited disorder that causes cysts to be formed on the nephrons, or functioning units, of the kidneys. The cysts hamper the regular functioning of the kidney.

Other possible causes of chronic kidney failure include **kidney cancer**, obstructions such as **kidney stones**, **pyelonephritis**, reflux nephropathy, **systemic lupus erythematosus**, **amyloidosis**, sickle cell anemia, **Alport syndrome**, and oxalosis.

Initially, symptoms of chronic kidney failure develop slowly. Even individuals with mild to moderate kidney failure may show few symtpoms in spite of increased urea in their blood. Among the symptoms that may be present at this point are frequent urination during the night and high blood pressure.

Most symptoms of chronic kidney failure are not apparent until **kidney disease** has progressed significantly. Common symptoms include:

- Anemia. The kidneys are responsible for the production of erythropoietin (EPO), a hormone which stimulates red cell production. If kidney disease causes shrinking of the kidney, this red blood cell production is hampered.
- Bad breath or a bad taste in mouth. Urea, or waste products, in the saliva may cause an ammonia-like taste in the mouth.
- Bone and joint problems. The kidneys produce vitamin D, which aids in the absorption of calcium and keeps bones strong. For patients with kidney failure, bones may become brittle, and in the case of children, normal growth may be stunted. Joint pain may also occur as a result of unchecked phosphate levels in the blood.
- Edema. Puffiness or swelling around the eyes, arms, hands, and feet.
- Frequent urination.
- Foamy or bloody urine. Protein in the urine may cause it to foam significantly. Blood in the urine may indicate bleeding from diseased or obstructed kidneys, bladder, or ureters.
- Headaches. High blood pressure may trigger headaches.
- Hypertension, or high blood pressure. The retention of fluids and wastes causes blood volume to increase, which in turn, causes blood pressure to rise.
- Increased fatigue. Toxic substances in the blood and the presence of anemia may cause feelings of exhaustion.
- Itching. Phosphorus, which is typically eliminated in the urine, accumulates in the blood of patients with kidney failure. This heightened phosphorus level may cause itching of the skin.

WWW.BOOKBAZ.IR

- Lower back pain. Pain where the kidneys are located, in the small of the back below the ribs.
- Nausea, loss of appetite, and vomiting. Urea in the gastric juices may cause upset stomach. This can lead to malnutrition and weight loss.

Diagnosis

Kidney failure is typically diagnosed and treated by a nephrologist, a doctor that specializes in treating the kidneys. The patient that is suspected of having chronic kidney failure will undergo an extensive blood work-up. A blood test will assess the levels of creatinine, blood urea nitrogen (BUN), uric acid, phosphate, **sodium**, and potassium in the blood. Urine samples will also be collected, usually over a 24-hour period, to assess protein loss.

Uncovering the cause of kidney failure is critical to proper treatment. A full assessment of the kidneys is necessary to determine if the underlying disease is treatable and if the kidney failure is chronic or acute. An x ray, MRI, computed tomography scan, **ultrasound**, renal biopsy, and/or arteriogram of the kidneys may be employed to determine the cause of kidney failure and level of remaining kidney function. X rays and ultrasound of the bladder and/or ureters may also be taken.

Treatment

Chronic kidney failure is an irreversible condition. Hemodialysis, peritoneal dialysis, or **kidney transplantation** must be employed to replace the lost function of the kidneys. In addition, dietary changes and treatment to relieve specific symptoms such as anemia and high blood pressure are critical to the treatment process.

Hemodialysis

Hemodialysis is the most frequently prescribed type of dialysis treatment in the United States. Most hemodialysis patients require treatment three times a week, for an average of three to four hours per dialysis "run" depending on the type of dialyzer used and their current physical condition. The treatment involves circulating the patient's blood outside of the body through an extracorporeal circuit (ECC), or dialysis circuit. The dialysis circuit consists of plastic blood tubing, a two-compartment filter known as a dialyzer, or artificial kidney, and a dialysis machine that monitors and maintains blood flow and administers dialysate, a chemical bath used to draw waste products out of the blood. The patient's blood leaves and enters the body through two needles inserted into the patient's vein, called an access site, and is pushed through the blood compartment of the dialyzer. Once inside of the dialyzer, excess fluids and toxins are pulled out of the bloodstream and into the dialysate compartment, where they are carried out of the body. At the same time, electrolytes and other chemicals in the dialysate solution move from the dialysate into the bloodstream. The purified, chemically-balanced blood is then returned to the body.

Peritoneal dialysis

In peritoneal dialysis (PD), the patient's peritoneum, or lining of the abdomen, acts as a blood filter. A catheter is surgically inserted into the patient's abdomen. During treatment, the catheter is used to fill the abdominal cavity with dialysate. Waste products and excess fluids move from the patient's bloodstream into the dialysate solution. After a waiting period of six to 24 hours, depending on the treatment method used, the waste-filled dialysate is drained from the abdomen, and replaced with clean dialysate. There are three types of peritoneal dialysis, which vary by treatment time and administration method: Continuous Ambulatory Peritoneal Dialysis (CAPD), Continuous Cyclic Peritoneal Dialysis (CCPD), and Intermittent Peritoneal Dialysis (IPD).

Kidney transplantation

Kidney transplantation involves surgically attaching a functioning kidney, or graft, from a brain dead organ donor (a cadaver transplant), or from a living donor, to a patient with ESRD. Patients with chronic renal disease who need a transplant and don't have a living donor register with UNOS (United Network for Organ Sharing), the federal organ procurement agency, to be placed on a waiting list for a cadaver kidney transplant. Kidney availability is based on the patient's health status. When the new kidney is transplanted, the patient's existing, diseased kidneys may or may not be removed, depending on the circumstances surrounding the kidney failure. A regimen of immunosuppressive, or anti-rejection medication, is required after transplantation surgery.

Dietary management

A diet low in sodium, potassium, and phosphorous, three substances that the kidneys regulate, is critical in managing kidney disease. Other dietary restrictions, such as a reduction in protein, may be prescribed depending on the cause of kidney failure and the type of dialysis treatment employed. Patients with chronic kidney failure also need to limit their fluid intake.

KEY TERMS

End-stage renal disease (ESRD)—Total kidney failure; chronic kidney failure is diagnosed as ESRD when kidney function falls to 5–10% of capacity.

Nephrotic syndrome—Characterized by protein loss in the urine, low protein levels in the blood, and fluid retention.

Ureters—The two ducts that pass urine from each kidney to the bladder.

Medications and dietary supplements

Kidney failure patients with **hypertension** typically take medication to control their high blood pressure. Epoetin alfa, or EPO (Epogen), a hormone therapy, and intravenous or oral iron supplements are used to manage anemia. A multivitamin may be prescribed to replace **vitamins** lost during dialysis treatments. **Vitamin D**, which promotes the absorption of **calcium**, along with calcium supplements, may also be prescribed.

Since 1973, Medicare has picked up 80% of ESRD treatment costs, including the costs of dialysis and transplantation and of some medications. To qualify for benefits, a patient must be insured or eligible for benefits under Social Security, or be a spouse or child of an eligible American. Private insurance and state Medicaid programs often cover the remaining 20% of treatment costs.

Prognosis

Early diagnosis and treatment of kidney failure is critical to improving length and quality of life in chronic kidney failure patients. Patient outcome varies by the cause of chronic kidney failure and the method chosen to treat it. Overall, patients with chronic kidney disease leading to ESRD have a shortened lifespan. According to the United States Renal Data System (USRDS), the lifespan of an ESRD patient is 18–47% of the lifespan of the age-sex-race matched general population. ESRD patients on dialysis have a lifespan that is 16–37% of the general population.

The demand for kidneys to transplant continues to exceed supply. In 1996, over 34,000 Americans were on the UNOS waiting list for a kidney transplant, but only 11,330 living donor and cadaver transplants were actually performed. Cadaver kidney transplants have a 50% chance of functioning nine years, and living donor kidneys that have two matching antigen pairs have a 50% chance of functioning for 24 years. However, some transplant grafts have functioned for over 30 years.

Chronic leukemias *see* **Leukemias, chronic**

Chronic obstructive pulmonary disease

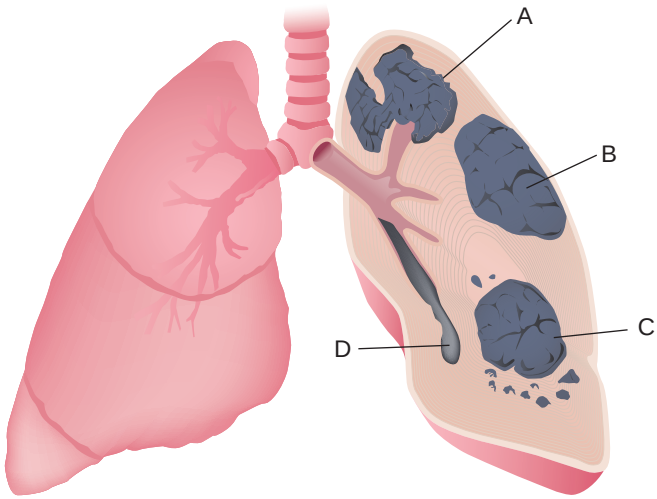
Definition

Chronic obstructive pulmonary disease (COPD) refers to two related, progressive diseases of the respiratory system, chronic **bronchitis** and **emphysema**. Emphysema is the enlargement and destruction of the air sacs (alveoli) of the lungs. Chronic bronchitis is ongoing inflammation that eventual results in narrowing of the airways. These are gradually progressive and permanent disease conditions in which there is persistent difficulty in expelling (exhaling) air from the lungs resulting in loss of lung function. Because **smoking** is the major cause of both diseases, chronic bronchitis and emphysema often occur together in the same individual.

Demographics

Almost all people with COPD are over age 40, and the highest rate of the disease is among those age 65 and older. More men than women have COPD, but at least in the United States the difference in rates between genders is narrowing.

WWW.BOOKBAZ.IR



A. Lung cancer. B. Pneumonia. C. Emphysema. D. Phlegm from chronic bronchitis. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

The exact prevalence of COPD in the United States is unknown, although it is estimated to be about 10% of the population, and some experts believe that that is an underestimate because many cases go unreported. According to the United States Centers for Disease Control and Prevention (CDC), COPD was the fourth leading cause of death in the United States in 2008. Internationally, COPD was the fifth leading cause of death. International prevalence estimates vary from a high of about 20% in South Africa to a low of about 5% in parts of Germany. Chronic bronchitis is about four times more common than emphysema.

Description

The lungs are the site where oxygen enters the blood and carbon dioxide is removed from the blood. Healthy lungs perform this process, known as gas exchange, efficiently. When air is inhaled through the nose or mouth, it moves through the windpipe (trachea) to large bronchial tubes (bronchi) then through smaller tubes (bronchioles). At the ends of the bronchioles are small air sacs (alveoli). In healthy lungs, the alveoli and the bronchi are springy and elastic. Much like a balloon, the alveoli can fill up with inhaled air and deflate when air is exhaled. In people with COPD, the alveoli lose their elasticity and shape so that a smaller volume of air moves in or out with each breath. COPD develops slowly over many years. Once it develops, COPD is irreversible (permanent); the damage done to the lungs, airways, and walls of the airways cannot be repaired by the body.

Chronic bronchitis

In chronic bronchitis, prolonged exposure to irritants such as smoke or airborne chemicals cause airways to lose their elasticity and narrow. Inflammation also causes glands that line the bronchi to produce excessive amounts of mucus, further narrowing the airways and blocking airflow. The result is often a chronic **cough** that produces sputum (mainly mucus) and **shortness of breath**. Cigarette smoke and other irritants also damage the cilia, small hair-like projections that move bacteria and foreign particles out of the airways. When the cilia are damaged, there is an increased the risk of lung infections.

Emphysema

Emphysema is a disease in which cigarette smoke causes an overproduction of the enzyme elastase, one of the immune system's infection-fighting biochemicals. This results in irreversible destruction of a protein in the lung called elastin. Elastin is essential in maintaining the structure of the walls of the alveoli, the terminal small air sacs of the respiratory system where gas exchange takes place. As the walls of the alveoli rupture, the number of alveoli is reduced and many of those remaining are enlarged. This reduces the surface area for gas exchange and makes the lungs of the patient with emphysema less elastic and overinflated. Because higher pressure inside the chest that must be developed to force air out of the less-elastic lungs, the bronchioles, small air tubes of the respiratory system, tend to collapse during exhalation, blocking air flow. Stale air gets trapped in the air sacs and less fresh air can be inhaled.

Risk factors

Cigarette smoking is the greatest risk factor for developing COPD and accounts for about 80% of all cases. Cigar and pipe smoking also can cause COPD. Exposure to airborne pollutants (e.g., chemicals, industrial dust) in the work place also increases risk. Coal mining, cotton textile manufacturing, and gold mining are among the occupations where risk is increased, but the effects of these occupational exposures are lower than the effects of cigarette smoke. There is some debate about the role of exposure to air pollution in the development of COPD, but it is agreed to be a less important as a risk factor than cigarette smoking.

Causes and symptoms

The primary cause of COPD is cigarette smoking, along with the smoking of pipes and cigars. Secondary (passive) exposure to cigarette smoke is also a contributing factor to COPD. Occupational chemicals,

KEY TERMS

Alveoli—Terminal air sacs of the respiratory system, where gas (oxygen and carbon dioxide) exchange occurs.

Bronchi—Large air tubes of the respiratory system.

Bronchioles—Small air tubes of the respiratory system.

Bronchodilators—Drugs that open wider the bronchial tubes of the respiratory system.

Corticosteroids—A group of hormones that are used as drugs to block inflammation.

Forced expiratory volume (FEV1)—The maximum amount of air expired in one second.

Spirometer—An instrument used by a doctor to perform a breathing test.

Vital capacity (VC)—The largest amount of air expelled after one's deepest inhalation.

dusts, and airborne particulates in the workplace also have been documented to be factors that can lead to the disease, as have air pollutants in the home. Outdoor air pollution has not been documented to be a significant factor to COPD, although such pollution is never good to anyone's lungs, especially those at risk for developing COPD.

Genetic and hereditary factors are also a consideration in developing COPD. One form of emphysema is known to run in families. People with this type of emphysema have a hereditary deficiency of a blood component, an enzyme inhibitor called alpha-1-antitrypsin (AAT). This type of emphysema is sometimes called early onset emphysema because it can appear when a person is as young as 30–40 years old. This type of emphysema is estimated to account for only 1–3% of all cases of emphysema. The risk of developing emphysema for an AAT-deficient individual who also smokes is much greater than for others.

The symptoms of COPD develop gradually, usually over years. The most common symptoms of chronic bronchitis are cough, production of sputum, and shortness of breath, especially with **exercise**. People with COPD also may experience **wheezing** and tightness in the chest. In emphysema, shortness of breath on exertion is the predominant early symptom. Coughing is usually minor, and there is little sputum. As emphysema progresses, shortness of breath occurs with less exertion, and eventually may be present even when at rest. At this point, a sputum-producing cough may also occur. Either chronic bronchitis or emphysema can lead to **respiratory failure**, a condition in which there occurs a dangerously low level of oxygen or a serious excess of carbon dioxide in the blood.

Diagnosis

A history of heavy smoking is not enough to diagnose COPD. The first step in making a diagnosis is a good medical evaluation, including a medical history and a **physical examination** of the chest using a stethoscope. This may be followed by a variety of tests to evaluate lung function.

Tests

A pulmonary function test is a measure of how much air is passing into and out of the lungs. Using a spirometer, an instrument that measures the air taken into and exhaled from the lungs, the doctor will determine two important values: (1) vital capacity (VC), the largest amount of air expelled after the deepest inhalation, and (2) forced expiratory volume (FEV1), the maximum amount of air expired in one second. The pulmonary function test can be performed in the doctor's office. A person with chronic cough and sputum production but normal **spirometry** results may simply be at risk for COPD. With mild COPD, the test usually shows mild airflow limitation, and the patient may not be aware that airflow in the lungs is reduced. With moderate COPD, the pulmonary function test shows that airflow limitation is worsening. The patient may have noticed that shortness of breath has worsened, particularly when walking fast or doing physical activity. Patients with severe or very severe COPD will have low volume readings.

Other tests used to diagnose COPD include diffusion studies, which determine how well oxygen in the air moves from the lungs into the blood. A blood sample may be taken to determine arterial blood gas. This test measures the amount of oxygen and carbon dioxide in the blood to see if these gases are being exchanged correctly. Low oxygen and high carbon dioxide levels are often indicative of chronic bronchitis, but not always of emphysema.

Chest x rays can detect only about half of the cases of emphysema. Chest x rays are rarely useful for diagnosing chronic bronchitis.

WWW.BOOKBAZ.IR

If infection is present, blood and sputum tests may be done to determine the cause of infection.

Many patients with lung disease also develop heart problems. An electrocardiogram (ECG) identifies signs of **heart disease**.

Treatment

Treatment for COPD is based on relieving symptoms, preventing complications, and improving a patient's overall health. The treatment varies depending on a patient's symptoms and stage of COPD. Treatment also may change over time and if a patient experiences complications or sudden onset of more severe symptoms.

Only two treatments have been found to help people with COPD breathe more easily. Quitting smoking helps ease symptoms and slow the progress of the disease. Physicians will urge all patients with COPD who smoke to quit smoking. Quitting will not reverses the COPD, but will make the decline in lung function slower.

Supplemental oxygen is the only therapy that has been demonstrated to reduce the number of deaths in patients with COPD. The treatment usually is reserved for patients who are unable to get adequate oxygen on their own. The oxygen may be delivered by a portable tank that allows the patient to be mobile outside the home, through a concentrator unit placed in the home, or through some combination. Some patients will receive oxygen some of the time, such as when short of breath. Others may receive it only at night. Using extra oxygen more than 15 hours a day helps people perform activities with less shortness of breath, remain more alert during the day, and protects the heart and other organs from damage.

Drugs

Medications frequently prescribed for COPD patients include:

- Bronchodilators. These agents open narrowed airways and offer significant symptomatic relief for many, but not all, people with COPD. There are three types of bronchodilators: Beta2 agonists, anticholinergic agents, and theophylline and its derivatives. Depending on the specific drug, a bronchodilator may be inhaled, injected, or taken orally.
- Corticosteroids. Corticosteroids, usually inhaled, block inflammation and are most useful for patients with chronic bronchitis with or without emphysema. Steroids are generally not useful in patients who have emphysema.
- Antibiotics. Antibiotics are frequently given at the first sign of a respiratory infection, such as increased sputum production or a change in color of sputum from clear to yellow or green.
- Vaccines. To prevent pulmonary infection from viruses and bacteria, people with COPD should be vaccinated against influenza each year at least six weeks before flu season and have a one-time pneumococcal (pneumonia) vaccine.
- Expectorants. These agents help loosen and expel mucus secretions from the airways.
- Diuretics. These drugs are given to prevent excess water retention in patients with associated right heart failure.
- Augmentation therapy (for emphysema due to AAT-deficiency only). Replacement AAT (Prolastin), derived from human blood which has been screened for viruses, is injected weekly or bimonthly for life.

Pulmonary rehabilitation

A structured, outpatient pulmonary **rehabilitation** program improves functional capacity in certain patients with COPD. Services may include general exercise training, administration of oxygen and **nutritional supplements**, intermittent mechanical ventilator support, continuous positive airway pressure, relaxation techniques, breathing exercises and techniques (such as pursed lip breathing), and methods for mobilizing and removing secretions.

Surgery

Surgical procedures for emphysema are very rare. They are expensive and often not covered by insurance. The great majority of patients cannot be helped by surgery, and no single procedure is ideal for those who can be helped.

Lung transplantation has been successfully employed in some patients with end-stage COPD. In the hands of an experienced team, the one-year survival rate is over 70% Lung transplantation is most often reserved for younger patients.

Lung volume reduction. These procedures remove 20–30% of severely diseased lung tissue; the remaining parts of the lung are joined together. Mortality rates can be as high as 15% and complication rates are even higher. When the operation is successful, patients report significant improvement in symptoms.

Alternatives

For both chronic bronchitis and emphysema, alternative practitioners recommend diet and nutritional supplements, a variety of herbal medicines, **hydrotherapy**, **acupressure** and **acupuncture**, **aromatherapy**, homeopathy, and **yoga**.

People with COPD may have more trouble breathing if they eat large meals because the stomach pushes on the diaphragm, the muscle that helps in breathing. Individuals with COPD also need to eat well-balanced **diets** because good **nutrition** helps fight infection. In the more severe stages of COPD, patients may experience weight loss and decreased muscle tissue, so these patients may need to eat high-calorie foods. Most people with COPD are encouraged to drink extra fluids to keep mucus thin and easier to cough up. Some have heart conditions and fluid retention and require fluid restriction.

Prognosis

COPD is a disease that can be treated and controlled, but not cured. Survival of patients with COPD is clearly related to the degree of their lung function when they are diagnosed and the rate at which they lose this function. Overall, the median survival is about 10 years for patients with COPD who have lost approximately two-thirds of their lung function at diagnosis.

Prevention

The most effective way to prevent COPD is to never smoke. Lifestyle modifications that can help prevent COPD, or improve function in COPD patients, include: quitting smoking, avoiding respiratory irritants and infections, avoiding allergens, maintaining good nutrition, drinking lots of fluids, avoiding excessively low or high temperatures and very high altitudes, maintaining proper weight, and exercising to increase muscle tone.

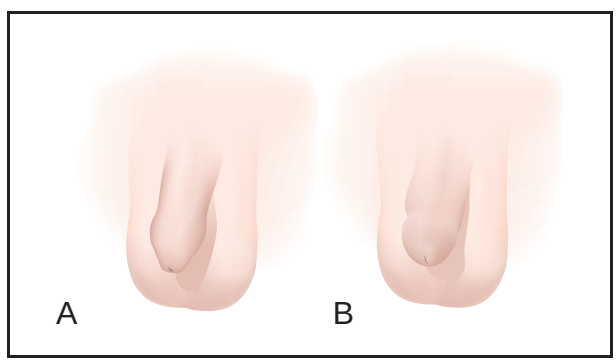
Circumcision

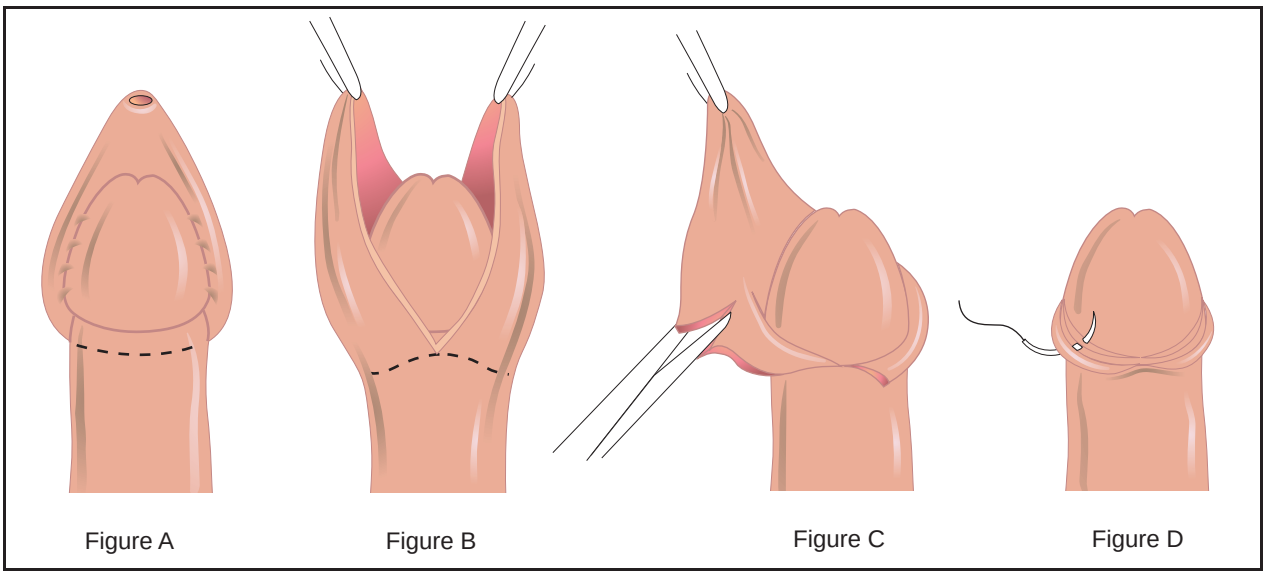
Definition

Circumcision is the surgical removal of the foreskin of the penis, or the prepuce of the clitoris.



An uncircumcised penis (A) and a circumcised penis (B). *(Illustration by Argosy, Inc. © Cengage Learning®.)*

WWW.BOOKBAZ.IR



A typical circumcision procedure involves the following steps: Figure A: The surgeon makes an incision around the foreskin. Figure B: The foreskin is then freed from the skin covering the penile shaft. Figure C: The surgeon cuts the foreskin to the initial incision, lifting the foreskin from the mucous membrane. Figure D: The surgeon sutures the top edge of the skin that covers the penile shaft and the mucous membrane. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Purpose

In the United States, circumcision in infant boys is performed for social, medical, or cultural/religious reasons. Once a routine operation urged by pediatricians and obstetricians for newborns in the middle of the twentieth century, the American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) stated in 1983 that "there is no absolute medical indication for routine circumcision of the newborn." This position was reiterated by the AAP in 1999 and again in 2005. Therefore, circumcision has become an elective option that parents make for their sons on an individual basis. Families who practice Judaism or Islam may select to have their sons circumcised as a religious practice. Others may choose circumcision for medical benefits.

Female circumcision (also known as **female genital mutilation**) is usually performed for cultural and social reasons by family members and others who are not members of the medical profession; it is performed without **anesthesia**. Not only is the prepuce of the clitoris removed, but often the vaginal opening is sewn to make it smaller. This practice is supposed to ensure the virginity of a bride on her wedding day. It also prevents the woman from achieving sexual pleasure during coitus. This practice is not universally approved by the medical profession and is considered by many to be a human rights violation. There is absolutely no medical indication for female circumcision on any grounds.

Some of the medical reasons parents of male infants choose circumcision are to protect against infections of the urinary tract and the foreskin, prevent cancer, lower the risk of getting sexually transmitted diseases, and prevent **phimosis** (a tightening of the foreskin that may close the opening of the penis). Though studies indicate that uncircumcised boys under the age of five are 20 times more likely than circumcised boys to have urinary tract infections (UTIs), the rate of incidence of UTIs is quite low and treatable with **antibiotics**. There are also indications that circumcised men are less likely to suffer from **penile cancer**, inflammation of the penis, or to contract sexually transmitted diseases. Good hygiene usually prevents most infections of the penis and actual incidence of sexually transmitted diseases is low. Phimosis and penile cancer are rare, even in men who have not been circumcised. Education and **safe sex** practices can prevent sexually transmitted diseases in ways that a surgical procedure cannot because these are diseases acquired through risky behaviors.

Research has indicated a 60% decrease in HIV transmission among circumcised men compared to uncircumcised men, whose foreskins have higher concentrations of cells that are targeted specifically by

HIV. Genital hygiene and safe sex practices are still crucial to preventing the spread of HIV.

Another study found that circumcised men who engaged in risky sexual behaviors were less likely to contract penile **human papillomavirus** (HPV), which has been implicated in the incidence of **cervical cancer** in women. There was little difference between circumcised and uncircumcised men's incidence of the virus if the men were in a monogamous relationship.

With these factors in mind, the American Academy of Pediatrics has issued a policy statement that maintains that though there is existing scientific evidence that indicates the medical benefits of circumcision, the benefits are not strong enough to recommend circumcision as a routine practice.

Demographics

In the United States, the Centers for Disease Control and Prevention (CDC) reports that circumcision was estimated to be performed in hospitals for 58% of newborn males in 2010, reduced by 10% compared to 1979 estimates; this percentage varies among ethnic and religious affiliations. Circumcision rates are much lower for the rest of the industrialized world. In Britain, it is only done for religious practices or to correct a specific medical condition of the penis.

Description

The penis consists of a cylindrical shaft with a rounded head called the glans. A groove called the coronal sulcus is found between the shaft and the glans. The foreskin of the penis covers and protects the glans and shields it from irritation by urine, feces, and foreign materials. It also protects the urinary opening against infection and incidental injury. A retractable foreskin can be pulled back behind the coronal sulcus to expose the glans.

In circumcision of infants, the foreskin is pulled tightly into a specially designed clamp, which forces the foreskin away from the broadened tip of the penis. The clamp applies pressure that stops bleeding from blood vessels that supply the foreskin. In older boys or adults, an incision is made around the base of the foreskin, the foreskin is pulled back, and then it is cut away from the tip of the penis. Stitches are usually used to close the skin edges.

Circumcision should not be performed on infants with certain deformities of the penis that may require a portion of the foreskin for repair. The most common condition for surgery using the foreskin is hypospadias, a congenital deformity of the penis where the urinary tract opening is not at the tip of the glans. Also, infants with a large hydrocele, or **hernia**, may suffer complications through circumcision. Premature infants and infants with serious infections are also poor candidates to be circumcised, as are infants with **hemophilia**, other bleeding disorders, or whose mothers had taken **anticoagulant drugs**. In older boys or men, circumcision is a minor procedure and can be performed on virtually anyone without a serious illness or unusual deformity.

Medical circumcisions are performed in the hospital by a pediatrician for an infant or child. For an adult, a general surgeon or urologist may perform a circumcision, especially if there are other urinary tract repairs to be made.

A Jewish religious circumcision, a *Bris Milah*, is performed when an infant male is eight days old. It is conducted by a trained *mohel*, with family and friends present, in a non-medical setting.

Preparation

Despite a long-standing belief that infants do not experience serious **pain** from circumcision, physicians now believe that some form of local anesthesia is necessary. Over 80% of pediatric residents, 80% of family practice residents, and 60% of obstetric/gynecological residents are routinely given instruction on pain control for circumcisions. Local anesthesia is often injected at the base of the penis (dorsal penile nerve block) or under the skin around the penis (subcutaneous ring block). Both anesthetics block key nerves and provide significantly lowered perceived pain. EMLA cream (lidocaine 2.5% and prilocaine 2.5%) can also be used.

Aftercare

After circumcision, the wound should be washed daily. An antibiotic ointment or petroleum jelly may be applied to the site. If there is an incision, a wound dressing will be applied and should be changed each time the diaper is changed. Sometimes a plastic ring (ring block with local anesthetic) is applied to the base of the penis instead of a bandage. The ring will usually fall off in 5–8 days. The penis will heal in 7–10 days.

Infants who undergo circumcision may be fussy for some hours afterward, so parents should be prepared for crying, feeding problems, and sleep problems. Generally, these go away within a day. In older boys, the penis may be painful, but this will go away gradually. A topical anesthetic ointment or spray may be used to relieve this temporary discomfort and oral

WWW.BOOKBAZ.IR

KEY TERMS

Foreskin—A covering fold of skin over the tip of the penis.

Glans—The cone-shaped tip of the penis.

Hernia—Bulging of abdominal structures through an abnormal opening in the muscular wall.

Hydrocele—Collection of fluid in the scrotum.

Hypospadias—A congenital deformity of the penis where the urinary tract opening is not at the tip of the glans.

Phimosis—A tightening of the foreskin that may close the opening of the penis.

Prepuce—A fold like the foreskin that covers the clitoris; another name for foreskin.

acetaminophin may be administered for pain control. If the procedure is performed in a hospital operating room, dorsal penile blocks or caudal (spinal) blocks may be used to lessen pain and avoid use of pain medications. The AAP Task Force on Circumcision also recommends the use of nonpharmacologic interventions for pain such as a sucrose pacifier. A bruise may be seen on the penis, which typically disappears without treatment.

Results

When an infant or an adult is circumcised, the surgical wound should heal quickly, with normal urinary function resuming immediately. An infant or older child should have no complications. After a period of recovery, an adult male should be able to resume sexual intercourse normally.

Risks

Complications following newborn circumcision appear in between two and six of every 1,000 procedures. Most complications are minor. Bleeding occurs in half of the complications and is usually easy to control. Infections are rare and occur at the circumcision site, the opening to the bladder, or at the tip of the penis as a result of contact with urine or feces. Infections are indicated by **fever** and signs of inflammation, and are treatable with antibiotics.

There may be injuries to the penis itself, and these may be difficult to repair.

Complications as a result of circumcision are usually minor if the physician is experienced and makes sure the Mogen or Gomco clamps that are used are in good working order. Severe penile injuries are rare, but they are serious, and include penile **amputation** (partial or total), laceration, hemorrhage, and damage to the urinary tract. Other serious complications such as **meningitis**, penile **necrosis**, necrotizing fasciitis, and **sepsis** can occur. Some of these, like meningitis and sepsis, can even cause death.

Hidden complications also occur. Subcutaneous masses have been detected under the skin of the penis. These masses usually have no symptoms, but, left untreated, could lead to more serious outcomes. Physicians should examine the penis at every well-baby checkup during the first year. If a mass is detected, it can easily be removed under a local anesthesia and sent to a pathology lab.

Alternatives

The only alternative to this surgery is to make an informed decision not to have an infant circumcised. Some Jewish parents are even electing not to hold a *Bris Milah*, a religious circumcision, for their sons, and choosing instead to hold a *Brit Shalom*, a naming ceremony, similar to that given for their infant daughters.

Cirrhosis

Definition

Cirrhosis is a chronic degenerative disease in which normal liver cells are damaged and are then replaced by scar tissue.

Demographics

Cirrhosis is the seventh leading cause of disease-related death in the United States. It is the third most common cause of death in adults between the ages of 45 and 65. It is twice as common in men as in women. The disease occurs in more than half of all malnourished chronic alcoholics, and kills about 25,000 people a year. In Asia and Africa, however, most deaths from cirrhosis are due to chronic **hepatitis B**.

Description

Cirrhosis changes the structure of the liver and the blood vessels that nourish it. The disease reduces the liver's ability to manufacture proteins and process hormones, nutrients, medications, and poisons.

Cirrhosis gets worse over time and can become potentially life threatening. This disease can cause:

- excessive bleeding (hemorrhage)
- impotence
- liver cancer
- coma due to accumulated ammonia and body wastes (liver failure)
- sepsis (blood poisoning)
- death

Types of cirrhosis

Portal or nutritional cirrhosis is the form of the disease most common in the United States. About 30–50% of all cases of cirrhosis are this type. Nine out of every ten people who have nutritional cirrhosis have a history of **alcoholism**. Portal or nutritional cirrhosis is also called Laënnec's cirrhosis.

Biliary cirrhosis is caused by intrahepatic bile-duct diseases that impede bile flow. Bile is formed in the liver and is carried by ducts to the intestines. Bile then helps digest fats in the intestines. Biliary cirrhosis can scar or block these ducts. It represents 15–20% of all cirrhosis.

Various types of chronic hepatitis, especially hepatitis B and **hepatitis C**, can cause postnecrotic cirrhosis. This form of the disease affects up to 40% of all patients who have cirrhosis.

Disorders like the inability to metabolize iron and similar disorders may cause pigment cirrhosis (**hemochromatosis**), which accounts for 5–10% of all instances of the disease.

Risk factors

Most risk factors for cirrhosis can be prevented or avoided. The primary risk factors are alcohol and chronic liver infections, such as hepatitis B and C. People at high risk of contracting hepatitis B include those exposed to the virus through contact with blood and body fluids. This includes healthcare workers and intravenous (IV) drug users. In the past, people have contracted hepatitis C through blood transfusions. **Obesity** and poor **nutrition** are also significant risk factors.

Certain hereditary diseases can increase an individual's risk for cirrhosis. In most cases, these cannot be prevented or avoided but risk may be reduced with proper treatment of the disease or disorder.

Causes and symptoms

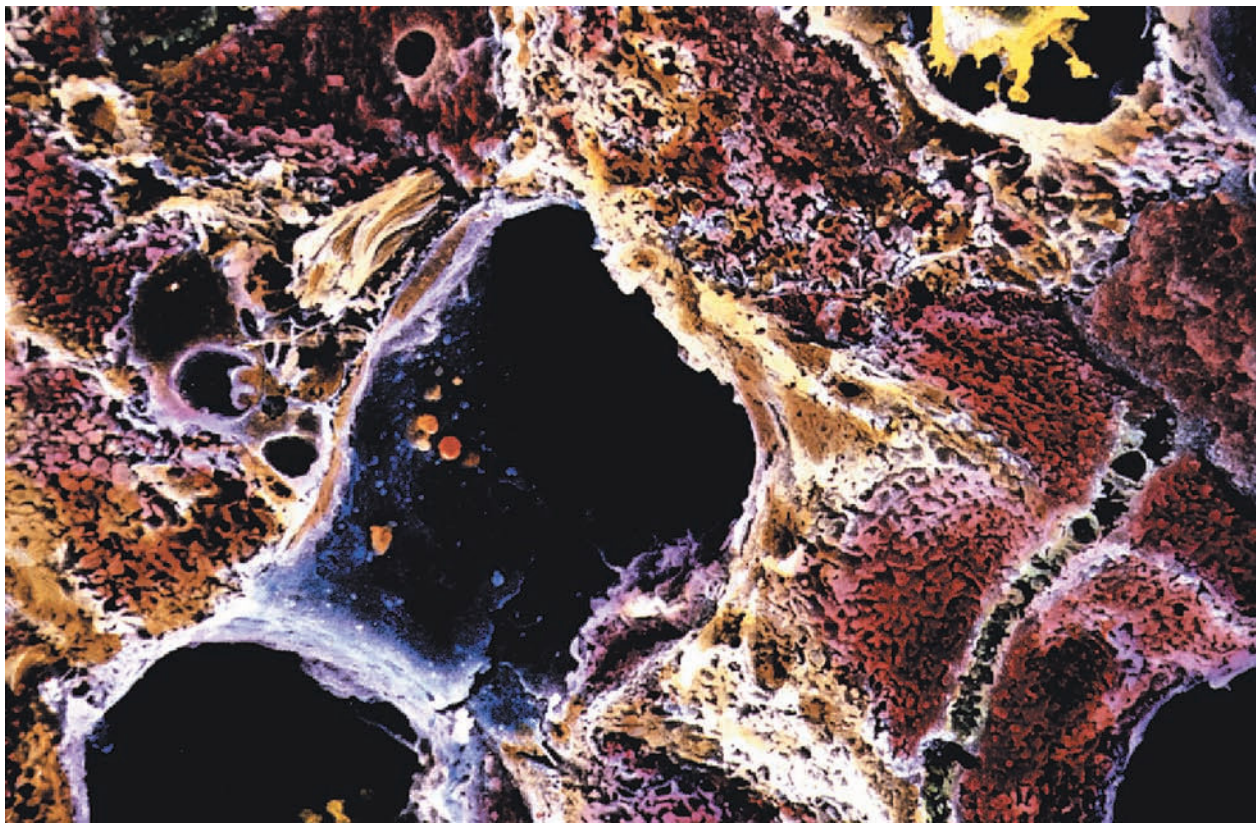
Long-term alcoholism is the primary cause of cirrhosis in the United States. Men and women respond differently to alcohol. Although most men can safely consume two to five drinks a day, one or two drinks a day can cause liver damage in women. Individual tolerance to alcohol varies, but people who drink more and drink more often have a higher risk of developing cirrhosis. In some people, one drink a day can cause liver scarring.

Chronic liver infections, such as hepatitis B and particularly hepatitis C, are commonly linked to cirrhosis. Cirrhosis resulting from chronic hepatitis has emerged as a leading cause of death among HIV-positive patients; in Europe, about 30% of HIV-positive patients are co-infected with a hepatitis virus.

Liver injury, reactions to prescription medications, exposure to toxic substances, and repeated episodes of **heart failure** with liver congestion can cause cirrhosis. The disorder can also be a result of diseases that run in families (inherited diseases) like:

- a lack of a specific liver enzyme ($alpha_1$-antitrypsin deficiency)
- the absence of a milk-digesting enzyme (galactosemia)
- an inability to convert sugars to energy (glycogen storage disease)
- an absorption deficit in which excess iron is deposited in the liver, pancreas, heart, and other organs (hemochromatosis)

WWW.BOOKBAZ.IR



A micrograph of a human liver showing tissue damaged by cirrhosis. *(Professor P. Motta/Photo Researchers, Inc.)*

- a disorder characterized by accumulations of copper in the liver, brain, kidneys, and corneas (Wilson's disease)

Obesity has recently been recognized as a risk factor in nonalcoholic hepatitis and cirrhosis. Some surgeons recommend that patients scheduled for weight-reduction surgery have a **liver biopsy** to evaluate the possibility of liver damage.

Poor nutrition increases a person's risk of developing cirrhosis. In about 10 out of every 100 patients, the cause of cirrhosis cannot be determined. Many people who have cirrhosis do not have any symptoms (often called compensated cirrhosis). Their disease is detected during a routine physical or when tests for an unrelated medical problem are performed. This type of cirrhosis can also be detected when complications occur (decompensated cirrhosis).

Symptoms of cirrhosis are usually caused by the loss of functioning liver cells or organ swelling due to scarring. The liver enlarges during the early stages of illness. The palms of the hands turn red and patients may experience:

- constipation
- diarrhea
- dull abdominal pain
- fatigue
- indigestion
- loss of appetite
- nausea
- vomiting
- weakness
- weight loss

As the disease progresses, the spleen enlarges and fluid collects in the abdomen (**ascites**) and legs (**edema**). Spider-like blood vessels appear on the chest and shoulders, and bruising becomes common. Men sometimes lose chest hair. Their breasts may grow and their testicles may shrink. Women may have menstrual irregularities.

Cirrhosis can cause extremely dry skin and intense **itching**. The whites of the eyes and the skin may turn yellow (**jaundice**), and urine may be dark yellow or brown. Stools may be black or bloody. Sometimes the patient develops persistent high blood pressure due to the scarring (portal **hypertension**). This type of

hypertension can be life threatening. It can cause veins to enlarge in the stomach and in the tube leading from the mouth to the stomach (esophagus). These enlarged veins are called varices, and they can rupture and bleed massively.

Other symptoms of cirrhosis include:

- anemia
- bleeding gums
- decreased interest in sex
- fever
- fluid in the lungs
- hallucinations
- lethargy
- lightheadedness
- muscle weakness
- musty breath
- painful nerve inflammation (neuritis)
- slurred speech
- tremors

If the liver loses its ability to remove toxins from the brain, the patient may have additional symptoms. The patient may become forgetful and unresponsive, neglect personal care, have trouble concentrating, and acquire new sleeping habits. These symptoms are related to ammonia intoxication and the failure of the liver to convert ammonia to urea. High protein intake in these patients can also lead to these symptoms.

Diagnosis

Examination

A patient's medical history can reveal illnesses or lifestyles likely to lead to cirrhosis. Liver changes can be seen during a **physical examination**. A doctor who suspects cirrhosis may order blood and urine tests to measure liver function. Because only a small number of healthy cells are needed to carry out essential liver functions, test results may be normal even when cirrhosis is present.

Tests

Computed tomography scans (CT), **ultrasound**, and other imaging techniques can be used during diagnosis. They can help determine the size of the liver, indicate healthy and scarred areas of the organ, and detect **gallstones**.

Procedures

Cirrhosis is sometimes diagnosed during surgery or by examining the liver with a laparoscope. This viewing device is inserted into the patient's body through a tiny incision in the abdomen.

Liver biopsy is usually needed to confirm a diagnosis of cirrhosis. In this procedure, a tissue sample is removed from the liver and is examined under a microscope in order to learn more about the organ.

A newer and less invasive test involves the measurement of hyaluronic acid in the patient's blood serum. The serum hyaluronic acid test is most useful in monitoring the progress of **liver disease**; it is unlikely to completely replace liver biopsy in the diagnosis of cirrhosis.

KEY TERMS

Biopsy—The removal of cells or tissue for examination from a surface or organ for examination under a microscope. A needle biopsy uses a long needle and syringe device to aspirate (remove by suction) a sample of the target tissue.

Computed tomography (CT) scan—A series of detailed images of areas inside the body taken at various angles; the images are created on a computer linked to an x-ray machine.

Jaundice—Yellowing of the skin and whites of the eyes when pigments normally eliminated by the liver collect in high amounts in the blood.

Treatment

The goal of treatment is to cure or reduce the condition causing cirrhosis, prevent or delay disease progression, and prevent or treat complications.

Salt and fluid intake are often limited, and activity is encouraged. A diet high in calories and moderately high in protein can benefit some patients. **Tube feedings** or vitamin supplements may be prescribed if the liver continues to deteriorate. Patients are asked not to consume alcohol.

Drugs

Iron supplements, **diuretics**, and **antibiotics** may be used for anemia, fluid retention, and ammonia accumulation associated with cirrhosis. Vasoconstrictors are sometimes needed to stop internal bleeding and **antiemetics** may be prescribed to control nausea.

Laxatives help the body absorb toxins and accelerate their removal from the digestive tract. **Beta blockers** may be prescribed to control cirrhosis-induced portal hypertension. Because the diseased

WWW.BOOKBAZ.IR

liver can no longer efficiently neutralize harmful substances, medications must be given with caution. Interferon medicines may be used by patients with chronic hepatitis B and hepatitis C to prevent post-hepatic cirrhosis.

Surgery

Medication that causes scarring can be injected directly into veins to control bleeding from varices in the stomach or esophagus. Varices may require a special surgical procedure called balloon tamponade ligation to stop the bleeding. Surgery may be required to repair disease-related throat damage. It is sometimes necessary to remove diseased portions of the spleen and other organs.

Liver transplants can benefit patients with advanced cirrhosis. However, the new liver will eventually become diseased unless the underlying cause of cirrhosis is removed. Patients with alcoholic cirrhosis must demonstrate a willingness to stop drinking before being considered suitable transplant candidates.

The incidence of **liver cancer** related to cirrhosis in the United States has increased 75% since the early 1990s. Partial surgical removal of the liver in patients with early-stage cancer of the liver appears to be as successful as transplantation, in terms of the 5-year survival rate.

Alternatives

Alternative treatments for cirrhosis are aimed at promoting the function of healthy liver cells and relieving the symptoms associated with the disease. Several herbal remedies may be helpful to cirrhosis patients. Dandelion (*Taraxacum officinale*) and rock-poppy (*Chelidonium majus*) may help improve the efficiency of liver cells. Milk thistle extract (*Silybum marianum*) may slow disease progression and significantly improve survival rates in alcoholics and other cirrhosis patients. Practitioners of homeopathy and **traditional Chinese medicine** can also prescribe treatments that support healthy liver function.

A balanced diet promotes regeneration of healthy liver cells. Eating five or six small meals throughout the day should prevent the sick or bloated feeling patients with cirrhosis often have after eating. Alcohol and **caffeine**, which destroy liver cells, should be avoided. So should any foods that upset the stomach. Patients with brain disease associated with cirrhosis should avoid excessive amounts of protein in the diet.

A patient can keep a food diary that describes what was eaten, when it was eaten, and how the patient felt afterwards. This diary can be useful in identifying foods that are hard to digest and in scheduling meals to coincide with the times the patient is most hungry.

Patients who have cirrhosis should weigh themselves every day and notify their doctor of a sudden gain of 5 lb (2.3 kg) or more. A doctor should also be notified if symptoms of cirrhosis appear in anyone who has not been diagnosed with the disease. A doctor should also be notified if a patient diagnosed with cirrhosis:

- vomits blood
- passes black stools
- seems confused or unresponsive
- shows signs of infection (redness, swelling, tenderness, pain)

Prognosis

Cirrhosis-related liver damage cannot be reversed, but further damage can be prevented by patients who:

- eat properly
- get enough rest
- do not consume alcohol
- remain free of infection

If the underlying cause of cirrhosis cannot be corrected or removed, scarring will continue. The liver will fail, and the patient will probably die within five years. Patients who stop drinking after being diagnosed with cirrhosis can increase their likelihood of living more than a few years from 40% up to 70%.

Prevention

Eliminating alcohol abuse could prevent 75–80% of all cases of cirrhosis.

Other preventive measures include:

- obtaining counseling or other treatment for alcoholism
- taking precautions (practicing safe sex, avoiding dirty needles) to prevent hepatitis
- getting immunizations against hepatitis if a person is in a high-risk group
- receiving appropriate medical treatment quickly when diagnosed with hepatitis B or hepatitis C
- having blood drawn at regular intervals to rid the body of excess iron from hemochromatosis
- using medicines (chelating agents) to rid the body of excess copper from Wilson's disease
- wearing protective clothing and following product directions when using toxic chemicals at work, at home, or in the garden

In 2001, research scientists identified the protein segment and method in which excess tissue grows in diseases like cirrhosis. With further study, the discovery might one day result in an oral or inhalable peptide for those with cirrhosis.

Cleft lip and palate

Definition

A cleft is a birth defect that occurs when the tissues of the lip and/or palate of the fetus do not fuse very early in **pregnancy**. A cleft lip, sometimes referred to as a harelip, is an opening in the upper lip that can extend into the base of the nostril. A cleft palate is an opening in the roof of the mouth.

Description

Babies born with cleft lips will have an opening involving the upper lip. The length of the opening ranges from a small notch, to a cleft that extends into the base of the nostril. Cleft lips may involve one or both sides of the lip.

Babies born with cleft palates have openings in the palate, which is the roof of the mouth. The size and position of the opening varies. The cleft may be only in the hard palate, the bony portion of the roof of the mouth, opening into the floor of the nose. It may be only in the soft palate, the soft portion of the roof of the mouth. The cleft palate may involve both the hard and soft palate and may occur on both sides of the center of the palate.

WWW.BOOKBAZ.IR

This infant has a unilateral cleft lip and palate. *(Custom Medical Stock Photo, Inc.)*

Babies may have cleft lips with or without cleft palates. Cleft palates may also occur without cleft lips.

The incidence of cleft lip and palate not associated with a syndrome is one in 700 newborns. Native Americans have an incidence of 3.6 in 1,000 newborns. The incidence among Japanese newborns is 2.1 in 1,000. The incidence among whites is one in 1,000 newborns. African Americans have an incidence of 0.3 in 1,000 newborns.

Causes and symptoms

Cleft lips and palates not associated with a syndrome are caused by a combination of genetic and environmental factors. Inheritance caused by such a combination is called multifactorial. The embryo inherits genes that increase the risk for cleft lip and/or palate. When an embryo with such genes is exposed to certain environmental factors the embryo develops a cleft.

The risk of a baby being born with a cleft lip or palate increases with the number of affected relatives and the number of relatives that have more severe clefts.

Environmental factors that increase the risk of cleft lip and palate include cigarette and alcohol use during pregnancy. Some drugs, such as phenytoin, **sodium** valproate, and methotrexate, also increase the incidence of clefting. The pregnant mother's **nutrition** may affect the incidence of clefting as well.

Babies born with a cleft lip will be seen to have an elongated opening in the upper lip. The size of this opening may range from a small notch in the upper lip to an opening that extends into the base of the nostril. The cleft lip may be below the right or left nostril or below both nostrils.

Babies born with a cleft palate will be seen to have an opening into the roof of the mouth. The size and position of the cleft varies and it may involve only the hard palate, or only the soft palate and may occur on both sides of the center of the palate.

In some cases the cleft palate will be covered with the normal lining of the mouth and can only be felt by the examiner.

Babies with cleft lips and palates have feeding difficulties, which are more severe in babies with cleft palates. The difficulty in feeding is due to the baby being unable to achieve complete suction. In the case of clefts of the hard palate, liquids enter the nose from the mouth through the opening in the hard palate.

A cleft palate also affects a child's speech, since the palate is necessary for speech formation. The child's speech pattern may still be affected despite surgical repair.

Ear infections are more common in babies born with cleft palates. The infections occur because the muscles of the palate do not open the Eustachian tubes that drain the middle ear. This allows fluid to collect and increases the risk of infection and **hearing loss**.

Teeth may also erupt misaligned.

Diagnosis

Cleft lip and palate can be diagnosed before birth by **ultrasound**. **Magnetic resonance imaging** (MRI) offers more accuracy for detecting cleft lip and palate, as it is a more detailed imaging method. It is particularly helpful in showing soft palate defects. In 2004, researchers reported discovery of a gene test for isolated cleft lip and cleft palate to help predict if parents who have one child with the isolated form of cleft lip or palate were likely to have a second child with the same defect. After birth, cleft lip and palate are diagnosed by physical exam.

Treatment

If cleft lip and/or palate are diagnosed by ultrasound before birth, further testing may be required to

diagnose associated abnormalities if present. Referral to a cleft team is essential. A cleft team consists of specialists in the management of babies with clefts and includes surgeons as well as nurses and speech therapists. Members of the team inform the parents of all aspects of management. Feeding methods are also discussed, since feeding is the first problem that must be dealt with. It may be possible to breastfeed a baby born with only a cleft lip, but babies born with cleft palates usually have more problems with feeding and frequently require special bottles and teats. A palatal obturator is a device that fits into the roof of the mouth, thus blocking the cleft opening and allowing easier suckling.

Surgery to repair cleft lips is sometimes performed after orthodontic treatment to narrow the gap in the upper lip. The orthodontic treatment can involve acrylic splints with or without screws or may involve the use of adhesive tape placed across the gap in the lip. The orthodontic treatment for cleft lip should be started within the first three weeks of life and continue until the cleft lip is repaired.

The timing of surgical cleft lip repair depends on the judgment of the surgeon who will perform the operation. The procedure is usually performed between one and three months of age. The goals of the operation are to close the gap in the upper lip, place **scars** in the natural skin curves and to repair muscle so that the lip appears normal during movement. The closure is done in the three layers (skin, muscle, and mucosa) that line the inside of the lip. At the time of the procedure, if the nose is shaped abnormally due to the cleft lip, it is also corrected. Sometimes further surgery may be needed on the lip and/or nose to refine the result.

The goals of the surgeon repairing a cleft palate are normal speech, normal facial growth, and hearing for the affected infant. The repair of the cleft palate is usually performed between three and 18 months of age. The timing may extend beyond this and varies with the type of cleft palate and center where the procedure is being performed. Depending of the type of cleft palate, more than one operation may be needed to close the cleft and improve speech.

Nonsurgical treatment of a cleft palate is available for patients who are at high risk for surgery and consists of a prosthetic appliance worn to block the opening in the palate.

Babies born with cleft palates are vulnerable to ear infections. Their Eustachian tubes do not effectively drain fluid from the middle ear so fluid accumulates and infection sets in. This may lead to hearing loss. These children require drainage tubes to be inserted to prevent fluid accumulation.

Babies born with clefts usually require orthodontic treatment between 13 and 18 years of age. They also require **speech therapy**.

Prognosis

Babies born with cleft lip and palate have a good prognosis, and approximately 80% will develop normal speech. There is no known means of preventing clefting. Good prenatal care is essential and avoiding harmful substances appear to reduce the risk.

Clenched fist injury

Definition

A clenched fist injury (CFI) is a bite wound on the hand, caused when a person's closed fist strikes the teeth of another person, usually in the course of a fight. CFIs are sometimes referred to as closed fist injuries or fight bites.

Description

Clenched fist injuries are most common over the metacarpo phalangeal joint. Their appearance is deceptive because they do not bleed heavily and the underlying injury is hidden by soft tissue when the patient opens his hand and straightens the injured finger. CFIs can, however, have serious consequences, including infection, **cellulitis**, inflammation of the bone or bone marrow (**osteomyelitis**), septic arthritis, and inflammation of the sheaths covering the tendons

WWW.BOOKBAZ.IR

KEY TERMS

Antibiotic—A chemical substance produced by a microorganism which can inhibit the growth of or kill other microorganisms.

Debridement—Surgical removal of damaged tissue and foreign objects from a wound.

I&D—Incision and drainage of a wound.

Irrigation—Cleansing a wound with large amounts of water and/or an antiseptic solution.

Parenteral—Administered inside the body but outside the digestive tract.

Tetanus toxoid—Tetanus toxoid is a vaccine used to prevent tetanus (also known as lockjaw).

of the hand (tenosynovitis). These may lead to permanent loss of function or **amputation**.

Most CFIs result in tissue injury due to the force of impact, ragged-edged tears in the skin resulting from contact with the teeth, and contamination of the wound by the bacteria in human saliva. As the patient opens his hand, the skin of the finger is pulled backward over the deeper part of the wound, thus sealing bacteria within the injured tissue. This sealing of the wound by normal motions of the finger is the reason why clenched fist injuries have the highest rate of infection of any human bite. The rate of infection of clenched-fist injuries varies from 15–50%.

Causes and symptoms

The causes of CFIs include fighting and other forms of aggressive behavior, often combined with drug or alcohol consumption.

The symptoms of clenched-fist injury include **pain** in the affected part of the hand and some stiffness of the injured finger with limitation of movement. If the patient has delayed getting medical treatment, there may be evidence of infection, including swelling, redness, and suppuration (a discharge of pus). The skin around the wound will be warm to the touch and **fever** may be present.

Diagnosis

Diagnosis of clenched fist injuries is usually made on the basis of the location of the injury and x-ray findings. The most common finding in CFI x rays is soft tissue swelling, but the x rays may also reveal air pockets in deep tissues or the joint spaces, fragments of teeth, fracture lines in the bones, or small loose bone chips. Diagnosis is often complicated by the fact that the patient will be reluctant to admit how the injury happened. The treating physician must maintain a high level of suspicion and often ask directly.

Treatment

Treatment of clenched fist injuries is complicated by several factors. One factor is the anatomical structure of the human hand, which contains many small closed spaces that make it easy for infection to spread and persist. Another is the number of disease-causing bacteria transmitted by human bites; at least 42 different species have been identified. In addition, CFIs typically do not receive immediate treatment because the patient is concerned about legal consequences. The longer the delay, the higher the chances of infection and permanent damage to the hand. Patients who wait longer than 24 hours to seek treatment or have signs of infection or damage to the tendon, joint capsule, or bones are usually referred immediately to a doctor who specializes in hand surgery.

The first step in treatment of clenched fist injury is irrigation, a procedure by which the wound is flushed with a stream of water under high pressure or with an antiseptic solution. Incision and drainage of the wound (I&D) may be required as well as **debridement**, the surgical removal of dead tissue and **foreign objects** from a wound. Careful examination of the depth of the wound is essential to proper treatment. The surgeon may need to enlarge the sides of the wound in order to make an accurate evaluation. The patient will be asked to move the affected joint through its full range of motion so that the surgeon can determine whether the tendon or joint capsule has been damaged. Following these procedures, the surgeon will pack the wound and put the hand in a splint. Bite **wounds** are never sutured (sewn shut) because of the possibility of enclosing bacteria inside the injury. After 24 hours, the packing will be removed and the hand reexamined for signs of infection.

If the wound has become infected, the patient is usually hospitalized and given parenteral (injectable) **antibiotics**. The wound is irrigated and examined to determine the extent of the injury. Cultures are taken for both aerobic (requiring air or oxygen to live) and

anaerobic (not requiring air or oxygen) species of bacteria. The cultures should be taken from areas deep in the wound rather than from the surface for greater accuracy. **Tetanus** toxoid should be given if the patient has not been immunized within the last 10 years. The patient should also receive treatment and follow-up for the rare possibility of HIV and hepatitis transmission. Although no well-documented cases of HIV transmission by human bites exist, the potential for transmission by this route is still present.

Infected clenched fist injuries usually contain several disease-causing bacteria, the most common being *Streptococcus pyogenes*, *Staphylococcus aureus*, *Bacteroides sp.*, *Peptostreptococcus sp.*, and *Eikenella corrodens*. Broad-spectrum antibiotics are usually given. Uninfected and relatively superficial CFIs may be treated with oral penicillin plus dicloxacillin or Augmentin. For infected CFIs, parenteral penicillin G is usually given together with nafcillin or cefuroxime. CFIs infected by drug-resistant strains of *S. aureus* may require treatment with vancomycin. While some human bite wounds do not require routine use of antibiotics, a 2004 study confirmed that puncture wounds, deeper lacerations and bites to the hand all have high infection rates which may be lowered by preventive use of antibiotics.

Prognosis

The prognosis depends on the patient's underlying state of health and compliance with treatment; depth of the wound; the involvement of the joint capsule or tendon; and the length of time before the wound is treated. The more superficial the wound and the faster the treatment, the better the prognosis.

Prevention

The best way to prevent clenched fist injuries is to avoid fist fights, intoxication, and association with people who practice these forms of behavior. If involved in a fist fight, people should avoid directing punches at their opponent's mouth. The next best preventive measure is to get medical treatment at once for a clenched-fist injury.

Club drugs

Definition

Club drugs are a diverse group of recreation-enhancing substances, used illegally, and usually consumed along with alcohol at raves, bars, clubs, concerts, or parties.

Description

Club drugs include Ecstasy (MDMA), GHB (gamma hydroxybutyrate, liquid ecstasy, soap), Rohypnol (flunitraxapam, roofies, a relative of Valium and Xanax), Ketamine (Special K, **Vitamin K**), **methamphetamine** (meth, speed, crystal, crank), and **LSD** (acid).

These drugs have separate, different actions. They are usually produced or imported illegally, so their strengths and purity are unknowable. Taken together, with alcohol, and consumed in intense social situations, their effects cannot be accurately predicted.

Ecstasy (XTC, X, E, MDMA), the most commonly used club drug, was patented in 1914 by Merck and not used for six decades. In the 1970s and 1980s, psychologists and therapists began experimenting with it for treating **anxiety**, depression, and post traumatic stress syndrome. Patients reported various

WWW.BOOKBAZ.IR

effects, including an increasing sense of empathy for self and others, **hallucinations**, and euphoria or ecstasy. Its use subsequently spread to the recreational drug subculture.

Ecstasy can increase body temperature, heart rate, and blood pressure, and can change perceptions of time, place and person. It can blunt sensations of thirst, allowing people to become dehydrated under its influence. It increases the amount of serotonin in the brain, producing euphoria, and/or anxiety and **paranoia**. After the drug wears off, temporarily decreased serotonin levels may leave users feeling depressed for days or even weeks.

MDMA is generally taken in doses of 125 milligrams, although effects are observable with as little as 60 milligrams. It is generally taken as tablets or capsules. Effects begin about an hour after ingestion, peak in three or four hours, and fade after six hours. Some users take a second dose to prolong the effects.

Dangers associated with Ecstasy include increased body temperature, complicated by excess physical activities such as dancing or immersion in hot tubs or saunas. **Dehydration**, increased heart rate and blood pressure are common. Because of its effects on serotonin in the brain, long-term Ecstasy users may have decreased memory. Other dangers include mixing the drug with alcohol, methamphetamine, or cocaine. People with heart problems, high blood pressure, or psychological disorders are at greater risk from taking this drug.

LSD (lysergic acid, acid) is a potent mood-changing drug that produces unpredictable effects, depending on the amount taken and the personality of the user. Effects range from euphoria to panic with intense hallucinations. Dangers associated with long term use of this drug include flash backs and **psychosis**.

Rohypnol (flunitrazepam, roofie) is a powerful sedative that is related to the sedative-tranquilizers, Valium and Xanax. It has been termed a "date rape" drug because it can cause "anterograde amnesia": those taking the substance may lose memory of events occurring under its effects. It is particularly dangerous to take Rohypnol with alcohol or other sedatives.

GHB (gamma hydroxybutyrate) is a substance with euphoric and depressant effects. There is a narrow range between safe, recreational use of GHB, overdose, producing **coma** or seizures, and life-threatening toxic dose.

Ketamine (special K, Vitamin K) is legitimately used as an animal tranquilizer. It can be taken orally, inhaled through the nose, or given intravenously and creates a sense of mind-body separation that can be experienced either pleasantly or as panic.

KEY TERMS

Hallucinogen—Substance that causes distorted perceptions and/or unreal dreams.

Neurotransmitter—Chemical in the brain that assists brain function.

Psychoactive—Substance that effects emotional and psychological perception in the brain.

Methamphetamine (meth, crystal, speed, crank) is a dangerously addictive stimulant. Taken orally, inhaled through the nose, or given intravenously, it produces an intense rush of euphoric stimulation followed by an overwhelming desire for more drug. It increases heart rate and blood pressure and may lead to **heart attack**, **heart failure**, and death. Research has shown that it damages brain cells that produce dopamine and serotonin, contributors to pleasure, memory and motivation. Prolonged or excessive use of methamphetamine can slow thinking, depress mood, and impair muscle strength and coordination. Emotional problems associated with the use of methamphetamine include **addiction**, paranoia, anxiety, and **insomnia**. Methamphetamine use has been growing in the United States throughout the 2000s.

Diagnosis

Substance abuse is defined by the *Diagnostic and Statistical Manual IV* as occurring when: users take a substance in larger amounts or over longer time periods than intended; a persistent and unsuccessful desire to cease usage; spending large quantities of time procuring the substance; reduction in other social activities; continued use of a substance despite physical or emotional problems caused by the substance; increased tolerance of the substance; withdrawal symptoms or increased use of a substance to avoid withdrawal symptoms.

Treatment

Treatment for problems associated with the use and abuse of club drugs include psychiatric, psychological, and substance abuse counseling, as well as emergency medical treatment for overdoses and complications.

Clubfoot

Definition

Clubfoot is a condition in which one or both feet are twisted into an abnormal position at birth. The condition is also known as talipes or talipes equinovarus.

Description

True clubfoot is characterized by abnormal bone formation in the foot. There are four variations of clubfoot, including talipes varus, talipes valgus, talipes equines, and talipes calcaneus. In talipes varus, the most common form of clubfoot, the foot generally turns inward so that the leg and foot look somewhat like the letter J. In talipes valgus, the foot rotates outward like the letter L. In talipes equinus, the foot points downward, similar to that of a toe dancer. In talipes calcaneus, the foot points upward, with the heel pointing down.

Clubfoot can affect one foot or both. Sometimes an infant's feet appear abnormal at birth because of the intrauterine position of the fetus birth. If there is no anatomic abnormality of the bone, this is not true clubfoot, and the problem can usually be corrected by applying special braces or casts to straighten the foot.

The ratio of males to females with clubfoot is 2.5 to 1. The incidence of clubfoot varies only slightly. In the United States, the incidence is approximately 1 in every 1,000 live births. A 1980 Danish study reported an overall incidence of 1.20 in every 1,000 children; by 1994, that number had doubled to 2.41 in every 1,000 live births. No reason was offered for the increase.

Person suffering from clubfoot. About one in every 1,000 newborns has some form of this birth defect. *(Photo Researchers, Inc.)*

Causes and symptoms

Experts do not agree on the precise cause of clubfoot. The exact genetic mechanism of inheritance has been extensively investigated using family studies and other epidemiological methods. No definitive conclusions have been reached, although a Mendelian pattern of inheritance is suspected. This may be due to the interaction of several different inheritance patterns, different patterns of development appearing as the same condition, or a complex interaction between genetic and environmental factors. The MSX1 gene has been associated with clubfoot in animal studies. However, these findings have not been replicated in humans.

WWW.BOOKBAZ.IR

A family history of clubfoot has been reported in 24.4% of families in a single study. These findings suggest the potential role of one or more genes being responsible for clubfoot.

Several environmental causes have been proposed for clubfoot. Obstetricians feel that intrauterine crowding causes clubfoot. This theory is supported by a significantly higher incidence of clubfoot among twins compared to singleton births. Intrauterine exposure to the drug misoprostol has been linked with clubfoot. Misoprostol is commonly used when trying, usually unsuccessfully, to induce abortion in Brazil and in other countries in South and Central America. Researchers in Norway have reported that males who are in the printing trades have significantly more offspring with clubfoot than men in other occupations. For unknown reasons, **amniocentesis**, a prenatal test, has also been associated with clubfoot. One international study published in 2004 reported that amniocentesis done at 13 weeks of gestation was associated with a fourfold increase in the risk of clubfoot. The infants of mothers who smoke during **pregnancy** have a greater chance of being born with clubfoot than are offspring of women who do not smoke.

True clubfoot is usually obvious at birth. The four most common varieties have been described. A clubfoot has a typical appearance of pointing downward and being twisted inwards. Since the condition starts in the first trimester of pregnancy, the abnormality is quite well established at birth, and the foot is often very rigid. Uncorrected clubfoot in an adult causes only part of the foot, usually the outer edge, or the heel or the toes, to touch the ground. For a person with clubfoot, walking becomes difficult or impossible.

Diagnosis

True clubfoot is usually recognizable and obvious on **physical examination**. A routine x ray of the foot that shows the bones to be malformed or misaligned supplies a confirmed diagnosis of clubfoot. Ultrasonography is not always useful in diagnosing the presence of clubfoot prior to the birth of a child; however, **ultrasound** is increasingly used in the early 2000s to evaluate the severity of clubfoot after birth and monitor its response to treatment.

Treatment

Most orthopedic surgeons agree that the initial treatment of congenital (present at birth) clubfoot should be nonoperative. Nonsurgical treatment should begin in the first days of life to take advantage of the favorable fibroelastic properties of the foot's connective tissues, those forming the ligaments, joint capsules, and tendons. In a common treatment, a series of casts is applied over a period of months to reposition the foot into normal alignment. In mild cases, splinting and wearing braces at night may correct the abnormality.

Another treatment for clubfoot is the Ilizarov frame, named for the Russian physician who developed it in 1951. The Ilizarov frame has been used in the United States and Canada since 1981. It consists of two metal rings that encircle the leg to be corrected, wires that attach the rings to the bone, and metal rods between the rings that can be extended like a telescope. The frame must be applied by an orthopedic surgeon. After a week, the surgeon begins to lengthen the rods, usually at the rate of 1 mm per day. The frame must be kept in place for several months. Although the Ilizarov frame is somewhat cumbersome, it has been reported as giving satisfactory results in straightening clubfeet, particularly those untreated in infancy.

When clubfoot is severe enough to require surgery, the condition is usually not completely correctable, although significant improvement is possible. In the most severe cases, surgery may be required, especially when the Achilles tendon, which joins the muscles in the calf to the bone of the heel, needs to be lengthened. Because an early operation induces fibrosis, a scarring and stiffness of the tissue, surgery should be delayed until an affected child is at least three months old.

Much of a clubfoot abnormality can be corrected by the use of manipulation and casting during the first three months of life. Proper manipulative techniques must be followed by applications of appropriately molded plaster casts to provide effective and safe correction of most varieties of clubfoot. Long-term care by an orthopedist is required after initial treatment to ensure that the correction of the abnormality is maintained. Exercises, corrective shoes, or nighttime splints may be needed until the child stops growing.

Prognosis

With prompt, expert treatment, clubfoot is usually correctable. One group of French researchers found that 77% of the children they followed over a period of 11 to 18 years had good results from nonsurgical methods of treatment combined with **physical therapy**. Most individuals are able to wear regular shoes and lead active lives. If clubfoot is not appropriately treated, however, the abnormality may become

KEY TERMS

Enterovirus—Any of a group of viruses that primarily affect the gastrointestinal tract.

Cluster headache

Definition

Cluster headaches are characterized by an intense one-sided **pain** centered by the eye or temple. The pain lasts for one to two hours on average and may recur several times in a day.

Description

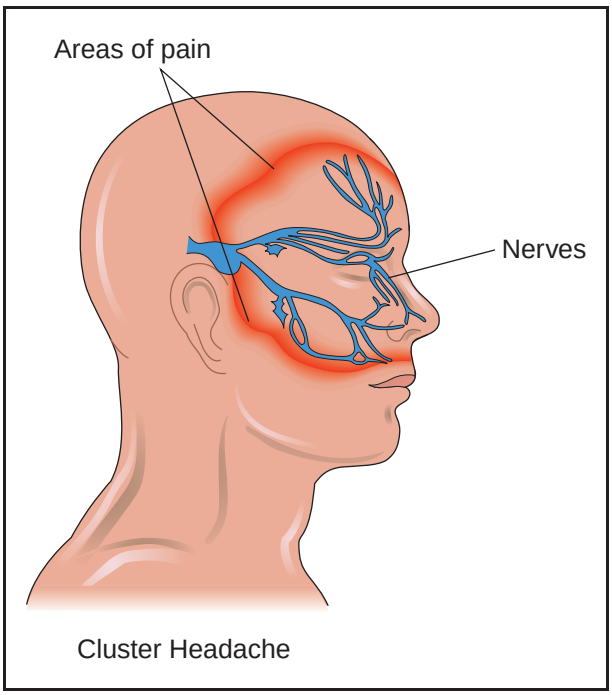
Cluster headaches have been known as histamine headaches, red migraines, and Horton's disease, among others. The constant factor is the pain, which transcends by far the distress of the more common tension-type **headache** or even that of a **migraine headache**.

Cluster headaches afflict less than 0.5% of the population and predominantly affect men; approximately 80% of sufferers are male. Onset typically occurs in the late 20s, but there is no absolute age restriction. Approximately 80% of cluster headaches are classified as episodic; the remaining 20% are considered chronic. Both display the same symptoms. However, episodic cluster headaches occur during one- to five-month periods followed by 6- to 24-month attack-free, or remission, periods. There is no such reprieve for chronic cluster headache sufferers.

Causes and symptoms

Biochemical, hormonal, and vascular changes induce cluster headaches, but why these changes

WWW.BOOKBAZ.IR



The primary cluster headache symptom is excruciating one-sided head pain located behind an eye or near the temple. Secondary symptoms include eye tearing, nasal congestion, and a runny nose. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

occur remains unclear. Episodic cluster headaches seem to be linked to changes in day length, possibly signaling a connection to the so-called biological clock. Alcohol, tobacco, histamine, or **stress** can trigger cluster headaches. Decreased blood oxygen levels (hypoxemia) can also act as a trigger, particularly during the night when an individual is sleeping. Interestingly, the triggers do not cause cluster headaches during remission periods.

The primary cluster headache symptom is excruciating one-sided head pain centered behind an eye or near the temple. This pain may radiate outward from the initial focus and encompass the mouth and teeth. For this reason, some cluster headache sufferers may mistakenly attribute their pain to a dental problem. Secondary symptoms, occurring on the same side as the pain, include eye tearing, nasal congestion followed by a runny nose, pupil contraction, and facial drooping or flushing.

Diagnosis

Cluster headache symptoms guide the diagnosis. A medical examination includes recording headache details, such as frequency and duration, when it occurs, pain intensity and location, possible triggers, and any prior symptoms. This history allows other potential problems to be discounted.

Treatment

Treatment for cluster headaches is composed of induction, maintenance, and symptomatic therapies. The first two therapies are prophylactic treatments, geared toward preventing headaches. Symptomatic therapy is meant to stop or shorten a headache.

Induction and maintenance therapies begin together. Induction therapy is intended to break the headache cycle with drugs such as **corticosteroids** (for example, prednisone) or dihydroergotamine. These drugs are not meant for long-term therapy, but rather as a jump-start for maintenance therapy. Maintenance therapy drugs include verapamil, lithium carbonate, ergotamine, and methysergide. These drugs have long-term effectiveness, but must be taken for at least a week before a response is observed. With long-term treatment, methysergide must be stopped for one month each year to avoid dangerous side effects (formation of fibrous tissue inside the abdominal artery, lungs, and heart valves).

Despite prophylactic treatment, headaches may still occur. Symptomatic therapy includes oxygen inhalation, sumatriptan injection, and application of local anesthetics inside the nose. Surgery is a last resort for chronic cluster headaches that fail to respond to therapy.

Alternatives

Since some cluster headaches are triggered by stress, **stress reduction** techniques, such as **yoga**, **meditation**, and regular **exercise**, may be effective. Some cluster headaches may be an allergic response triggered by food or environmental substances, therefore identifying and removing the allergen(s) may be key to resolution of the problem. Histamine is another suspected trigger of cluster headaches, and this response may be controlled with vitamin C and the bioflavonoids quercetin and bromelain (pineapple enzyme). Supplementation with essential fatty acids (EFA) will help decrease any inflammatory response.

Physical medicine therapies such as adjustments of the spine, craniosacral treatment, and massage at the temporomandibular joint (TMJ) can clear blockages, as can traditional Chinese medical therapies including **acupuncture**. Homeopathic treatment can also be beneficial. Nervous system relaxant herbs, used singly or in combination, can allow the central

KEY TERMS

Biological clock—A synonym for the body's circadian rhythm, the natural biological variations that occur over the course of a day.

Migraine headache—An intense throbbing pain that occurs on one or both sides of the head. The headache is usually accompanied by other symptoms, such as nausea, vomiting, and aversion to light.

Prophylactic—Referring to treatment that prevents symptoms from occurring.

Tension-type headache—A dull pain that seems to exert pressure on the head; the most common form of headache.

nervous system to relax as well as assist in peripheral nerve response. A few herbs to consider for relaxation are valerian (*Valeriana officinalis*), chamomile (*Matricaria recutita*), rosemary (*Rosemarinus officinalis*), and skullcap (*Scutellaria baicalensis*).

Prognosis

In general, drug therapy offers effective treatment.

Prevention

Avoiding triggers, adhering to medical treatment, and controlling stress can help ward off some cluster headaches.

Coagulation disorders

Definition

Coagulation disorders deal with disruption of the body's ability to control blood clotting. The most commonly known coagulation disorder is **hemophilia**, a condition in which patients bleed for long periods of time before clotting. There are other coagulation disorders with a variety of causes.

Description

Coagulation, or clotting, occurs as a complex process involving several components of the blood. Plasma, the fluid component of the blood, carries a number of proteins and coagulation factors that regulate bleeding. Platelets, small colorless fragments in the blood, initiate contraction of damaged blood vessels so that less blood is lost. They also help plug damaged blood vessels and work with plasma to accelerate blood clotting. A disorder affecting platelet production or one of the many steps in the entire process can disrupt clotting.

Coagulation disorders arise from different causes and produce different complications. Some common coagulation disorders are:

- Hemophilia, or hemophilia A (Factor VIII deficiency), an inherited coagulation disorder, affects about 20,000 Americans. This genetic disorder is carried by females but most often affects males.
- Christmas disease, also known as hemophilia B or Factor IX deficiency, is less common than hemophilia A with similar in symptoms.
- Disseminated intravascular coagulation disorder, also known as consumption coagulopathy, occurs as a result of other diseases and conditions. This disease accelerates clotting, which can actually cause hemorrhage.
- Thrombocytopenia is the most common cause of coagulation disorder. It is characterized by a lack of circulating platelets in the blood. This disease also includes idiopathic thrombocytopenia.
- Von Willebrand's disease is a hereditary disorder with prolonged bleeding time due to a clotting factor deficiency and impaired platelet function. It is the most common hereditary coagulation disorder.
- Hypoprothrombinemia is a congenital deficiency of clotting factors that can lead to hemorrhage.
- Other coagulation disorders include Factor XI deficiency, also known as hemophilia C, and Factor VII deficiency. Hemophilia C afflicts one in 100,000

WWW.BOOKBAZ.IR

people and is the second most common bleeding disorder among women. Factor VII is also called serum prothrombin conversion accelerator (SPCA) deficiency. One in 500,000 people may be afflicted with this disorder that is often diagnosed in newborns because of bleeding into the brain as a result of traumatic delivery.

Causes and symptoms

Some coagulation disorders present symptoms such as severe bruising. Others will show no apparent symptoms, but carry the threat of severe internal bleeding.

Hemophilia

Because of its hereditary nature, hemophilia A may be suspected before symptoms occur. Some signs of hemophilia A are numerous large, deep **bruises** and **pain** and swelling of joints caused by internal bleeding. Patients with hemophilia do not bleed faster, just longer. A person with mild hemophilia may first discover the disorder with prolonged bleeding following a surgical procedure. If there is bleeding into the neck, head, or digestive tract, or bleeding from an injury, emergency measures may be required.

Mild and severe hemophilia A are inherited through a complex genetic system that passes a recessive gene on the female chromosome. Women usually do not show signs of hemophilia but are carriers of the disease. Each male child of the carrier has a 50% chance of having hemophilia, and each female child has a 50% chance of passing the gene on.

Christmas disease

Christmas disease, or hemophilia B, is also hereditary but less common than hemophilia A. The severity of Christmas disease varies from mild to severe, although mild cases are more common. The severity depends on the degree of deficiency of the Factor IX (clotting factor). Hemophilia B symptoms are similar to those of hemophilia A, including numerous, large and deep bruises and prolonged bleeding. The more dangerous symptoms are those that represent possible internal bleeding, such as swelling of joints, or bleeding into internal organs upon **trauma**. Hemophilia most often occurs in families with a known history of the disease, but occasionally, new cases will occur in families with no apparent history.

Disseminated intravascular coagulation

The name of this disorder arises from the fact that malfunction of clotting factors cause platelets to clot in small blood vessels throughout the body. This action leads to a lack of clotting factors and platelets at a site of injury that requires clotting. Patients with disseminated intravascular coagulation (DIC) will bleed abnormally even though there is no history of coagulation abnormality. Symptoms may include minute spots of hemorrhage on the skin, and purple patches or hematomas caused by bleeding in the skin. A patient may bleed from surgery or intravenous injection (IV) sites. Related symptoms include **vomiting**, seizures, **coma**, **shortness of breath**, **shock**, and severe pain in the back, muscles, abdomen, or chest.

DIC is not a hereditary disorder or a common one. It is most commonly caused by complications during **pregnancy** or delivery, overwhelming infections, acute leukemia, metastatic cancer, extensive **burns** and trauma, and even snakebites. There are a number of other causes of DIC, and it is not commonly understood why or how these various disorders can lead to the coagulation problem. What the underlying causes of DIC have in common is some factor that affects proteins, platelets, or other clotting factors and processes. For example, uterine tissue can enter the mother's circulation during prolonged labor, introducing foreign proteins into the blood, or the venom of some exotic snakes can activate one of the clotting factors. Severe head trauma can expose blood to brain tissue. No matter the cause of DIC, the results are a malfunction of thrombin (an enzyme) and prothrombin (a glycoprotein), which activate the fibrinolytic system, releasing clotting factors in the blood. DIC can alternate from hemorrhage to thrombosis, and both can exist, which further complicates diagnosis and treatment.

Thrombocytopenia

Thrombocytopenia may be acquired or congenital. It represents a defective or decreased production of platelets. Symptoms include sudden onset of small spots of hemorrhage on the skin, or bleeding into mucous membranes (such as nosebleeds). The disorder may also be evident as blood in vomit or stools, bleeding during surgery, or heavy menstrual flow in women. Some patients show none of these symptoms, but complain of **fatigue** and general weakness. There are several causes of thrombocytopenia, which is more commonly acquired as a result of another disorder. Common underlying disorders include leukemia, drug toxicity, or **aplastic anemia**, all of which lead to decreased or defective production of platelets in the bone marrow. Other diseases may destroy platelets outside the marrow. These include severe infection, disseminated intravascular coagulation, and **cirrhosis**

of the liver. The idiopathic form most commonly occurs in children, and is most likely the result of production of antibodies that cause destruction of platelets in the spleen and to a lesser extent the liver.

Von Willebrand's disease is caused by a defect in the Von Willebrand clotting factor, often accompanied by a deficiency of Factor VIII as well. It is a hereditary disorder that affects both males and females. In rare cases, it may be acquired. Symptoms include easy bruising, bleeding in small cuts that stops and starts, abnormal bleeding after surgery, and abnormally heavy menstrual bleeding. Nosebleeds and blood in the stool with a black, tarlike appearance are also signs of Von Willebrand's disease.

Hypoprothrombinemia

This disorder is a deficiency in prothrombin, or Factor II, a glycoprotein formed and stored in the liver. Prothrombin, under the right conditions, is converted to thrombin, which activates fibrin and begins the process of coagulation. Some patients may show no symptoms, and others will suffer severe hemorrhaging. Patients may experience easy bruising, profuse nosebleeds, postpartum hemorrhage, excessively prolonged or heavy menstrual bleeding, and postsurgical hemorrhage. Hypoprothrombinemia may also be acquired rather than inherited, and usually results from a **vitamin K** deficiency caused by liver diseases, newborn hemorrhagic disease, or a number of other factors.

Other coagulation disorders

Factor XI deficiency, or hemophilia C, occurs more frequently among certain ethnic groups, with an incidence of about one in 10,000 among Ashkenazi Jews. Nearly 50% of patients with this disorder experience no symptoms, but others may notice blood in their urine, nosebleeds, or bruising. Although joint bleeding seldom occurs, some factor XI patients will experience bleeding long after an injury occurs. Some women will experience prolonged bleeding after **childbirth**. Patients with factor VII deficiency vary greatly in their bleeding severity. Women may experience heavy menstrual bleeding, bleeding from the gums or nose, bleeding deep within the skin, and episodes of bleeding into the stomach, intestine, and urinary tract. Factor VII patients may also suffer bleeding into joints.

Diagnosis

Several blood tests can be used to detect various coagulation disorders. There are hundreds of different tests a doctor can order to look for indications of specific diseases. In addition to blood tests, physicians will complete a medical history and **physical examination**. In the case of acquired coagulation disorders, information such as prior or current diseases and medications will be important in determining the cause of the blood disorder.

- Hemohilia A will be diagnosed with laboratory tests detecting presence of clotting factor VIII, factor IX, and others, as well as the presence or absence of clotting factor inhibitors.
- Christmas disease will be checked against normal bleeding and clotting time, as well as for abnormal serum reagents in factor IX deficiency. Other tests of prothrombin time and thromboplastic generation may also be ordered.
- There is no one test or group of tests that can always make (or exclude) a diagnosis of DIC. DIC can be diagnosed through a number of laboratory tests that measure concentration of platelets and fibrinogen in the blood with normal counts and prolonged prothrombin time. Other supportive data include diminished levels of factors V, fibrinogen, and VIII, decreased hemoglobin, and others. Since many of the test results also indicate other disorders, the physician may have to put together several results to reach a diagnosis of DIC. Serial tests may also be recommended, because a single examination at one moment in time may not reveal the process that is occurring.
- Tests for thrombocytopenia include coagulation tests revealing a decreased platelet count, prolonged bleeding time, and other measurements. If these tests indicate that platelet destruction is causing the disorder, the physician may order bone marrow examination.
- Von Willebrand's disease will be diagnosed with the assistance of laboratory tests which show prolonged bleeding time, absent or reduced levels of factor VIII, normal platelet count, and others.
- Hypothrombinemia is diagnosed with history information and the use of tests that measure vitamin K deficiency, deficiency of prothrombin, and clotting factors V, VII, IX, and X.
- Factor XI deficiency is diagnosed most often after injury-related bleeding. Blood tests can help pinpoint factor VII deficiency.

Treatment

In mild cases, treatment may involve the use of drugs that stimulate the release of deficient clotting factors. In severe cases, bleeding may only stop if the

WWW.BOOKBAZ.IR

KEY TERMS

Clotting factor—Also known as coagulation factors. Proteins in the plasma that serve to activate various parts of the blood clotting process by being transformed from inactive to active form.

Enzyme—A substance that causes a chemical reaction, usually a protein. Enzymes are secreted by cells.

Hemorrhage—Abnormal bleeding from the blood vessels.

Heparin—An anticoagulant, or blood clot "dissolver."

Idiopathic—Refers to a disease of unknown cause, and sometimes to a primary disease.

Metastatic—The term used to describe a secondary cancer, or one that has spread from one area of the body to another.

Serum reagents—Serum is fluid, or the fluid portion of the blood retained after removal of the blood cells and fibrin clot. Reagents are substances added to the serum to produce a chemical reaction.

Thrombosis—Formation of a clot in the blood that either blocks, or partially blocks a blood vessel. The thrombus may lead to infarction, or death of tissue, due to a blocked blood supply.

clotting factor that is missing is replaced through infusion of donated human blood in the form of fresh frozen plasma or cryoprecipitate.

- Hemophilia A in mild episodes may require infusion of a drug called desmopressin or DDAVP. Severe bleeding episodes will require transfusions of human blood clotting factors. Hemophiliacs are encouraged to receive physical therapy to help damaged joints and to exercise in non-contact sports such as swimming, bicycle riding, or walking.
- Christmas disease patients are treated similarly to hemophilia A patients. There are commercial products and human blood products available to provide coagulation. Cryoprecipitate was invented in 1965 to replace the need for whole plasma transfusions, which introduced more volume than needed. By the 1970s, people were able to infuse themselves with freeze-dried clotting factor. Superficial wounds can be cleaned and bandaged. Parents of hemophiliac children receiving immunizations should inform the vaccination provider in advance to decrease the possibility of bleeding problems. These children should probably not receive injections that go into the muscle.
- Treatment for disseminated intravascular coagulation patients is complicated by the large variety of underlying causes of the disorder. If at all possible, the physician will first treat this underlying disorder. If the patient is not already bleeding, this supportive treatment may eliminate the DIC. However, if bleeding is occurring, the patient may need blood, platelets, fresh frozen plasma, or other blood products. Heparin has been controversial in treating DIC, but it is often used as a last resort to stop hemorrhage. Heparin has not proven useful in treating patients with DIC resulting from heat stroke, exotic snakebites, trauma, mismatched transfusions, and acute problems resulting from obstetrical complications.
- Secondary acquired thrombocytopenia is best alleviated by treating the underlying cause or disorder. The specific treatment may depend on the underlying cause. Sometimes, corticosteroids or immune globulin may be given to improve platelet production.
- Von Willebrand's disease is treated by several methods to reduce bleeding time and to replace factor VIII, which consequently will replace the Von Willebrand factor. This may include infusion of cryoprecipitate or fresh frozen plasma. Desmopressin may also help raise levels of the Von Willebrand factor.
- Hypoprothrombinemia may be treated with concentrates of prothrombin. Vitamin K may also be produced, and in bleeding episodes, the patient may receive fresh plasma products.
- Factor XI (hemophilia C) is most often treated with plasma, since there are no commercially available concentrates of factor XI in the United States. Factor VII patients may be treated with prothrombin complex concentrates. Factor VII concentrate was not licensed in the United States and could only be used with special permission.

Alternatives

This can be a very severe condition and should be managed by a practitioner of alternative medicine in conjunction with a medical doctor; this condition should not be self managed. For patients known to suffer from hemophilia A or B and other bleeding disorders, avoidance of activities that can cause severe injury should be practiced. Comprehensive care

addresses the whole person by helping to deal with the psychosocial aspects of the disease.

Prognosis

The prognosis for patients with mild forms of coagulation disorders is normally good. Many people can lead a normal life and maintain a normal life expectancy. Without treatment of bleeding episodes, severe muscle and joint pain, and, eventually, damage can occur. Any incident that causes blood to collect in the head, neck, or digestive system can be very serious and requires immediate attention. DIC can be severe enough to cause clots to form and a **stroke** could occur. DIC is also serious enough to cause **gangrene** in the fingers, nose, or genitals. The prognosis depends on early intervention and treatment of the underlying condition. Hemorrhage from a coagulation disorder, particularly into the brain or digestive track, can prove fatal. In the past, patients who received regular transfusions of human blood products were subject to increased risk of **AIDS** and other diseases. However, efforts have been made since the early 1990s to ensure the safety of the blood supply.

Prevention

Prevention of coagulation disorders varies. Acquired disorders may only be prevented by preventing onset of the underlying disorder (such as cirrhosis). Hereditary disorders can be predicted with prenatal testing and **genetic counseling**. Prevention of severe bleeding episodes may be accomplished by refraining from activities that could cause injury, such as contact sports. Open communication with healthcare providers prior to procedures or tests that could cause bleeding may prevent a severe bleeding incident.

Coarctation of the aorta

Definition

Coarctation of the aorta (CoA) is a defect that develops in the fetus in which there is a narrowing of the aortic arch, the main artery that delivers blood from the left ventricle of the heart to the rest of the body. The word *coarctation* by itself means a narrowing or constriction. Coarctation of the aorta is diagnosed in both newborns and adults.

Demographics

Coarctation of the aorta is a relatively common congenital heart defect; it is found in 6–8% of infants with **congenital heart disease**. It is more common in boys, the male:female ratio being 2:1. Although researchers are still studying data related to race and ethnicity, there is some evidence that Asian babies are 2% less likely to have CoA than babies born in Europe, North America, or South America. In the United States, Native Americans have a lower rate of CoA than other racial and ethnic groups. The reason for these differences is not known.

Description

In humans, blood leaves the heart by way of the left ventricle and is distributed to the body by arteries. The aortic arch is the first artery to carry blood as it leaves the heart. Other arteries to the head and arms branch off the aortic arch. A narrowing of the aorta at any spot produces resistance to the flow of blood. This causes high blood pressure before the narrowing and low pressure below the narrowing (downstream). Parts of the body supplied by arteries that branch off the aortic arch before the narrowing have high blood pressure, while most of the lower body does not receive enough blood supply. Thus people with CoA have **hypertension** in their arms but low blood pressure in the legs and ankles. To compensate for the coarctation, the heart works harder, and the blood pressure rises.

There are three basic forms of CoA, defined by the location of the constriction or narrowing with regard to the ductus arteriosus, a blood vessel that connects the aortic arch and the pulmonary artery in the developing fetus. The purpose of this vessel is to bypass the lungs in the fetus, which are still filled with fluid. The ductus arteriosus normally closes shortly after birth when the newborn begins to breathe. Coarctation of the aorta may occur at the point where the ductus

WWW.BOOKBAZ.IR

arteriosus enters the aorta (ductal); before that point (preductal); or below that point (postductal):

- Ductal coarctation: This form of CoA usually first appears when the ductus arteriosus closes after birth.
- Preductal: This form of CoA is potentially life-threatening, as closure of the ductus arteriosus after birth may close off blood flow to the lower body.
- Postductal: This is the form of CoA most often seen in adults. It is associated with notching of the ribs, high blood pressure in the arms, and weak pulses in the legs.

The internal appearance of the narrowed part of the aorta varies somewhat from patient to patient. In some, the coarctation is localized whereas in others the narrowing involves a longer section of the aorta. The coarctation may look like a shelf of tissue partially closing off the aorta, or it may resemble a curtain or membrane with an irregular opening in the middle.

Risk factors

There are two major risk factors for coarctation of the aorta:

- The presence of one or more other heart defects, particularly ventricular septal defect, patent ductus arteriosus, or abnormalities of the bicuspid, mitral, or aortic valves in the heart.
- In females, Turner syndrome. Turner syndrome is a genetic disorder in which a girl or woman has only one of the two X chromosomes that determine female sex.

Causes and symptoms

In newborns with congenital **heart disease**, coarctation of the aorta develops while the baby is in the womb. The exact cause or trigger of the abnormal development is not completely understood. In rare cases, CoA can develop in adolescents or adults as a result of severe **trauma**, severe hardening of the arteries, or a rare disorder causing inflammation of the arteries known as Takayasu's arteritis.

Among the consequences of coarctation of the aorta is ventricular hypertrophy, an enlarging of the left ventricle in response to the increased back pressure of the blood and the demand for more blood by the body. Symptoms in infants include **shortness of breath** (dyspnea), difficulty in feeding, pale skin, heavy sweating, and poor weight gain. Older children may develop measurable hypertension; they may also display **fatigue**, shortness of breath, cold feet, headaches, nosebleeds, or a feeling of lameness in their legs.

Diagnosis

Children or adults with any of the following symptoms should see a doctor at once. Although these symptoms may have causes other than CoA, it is best to be checked, because early detection of CoA can be life-saving:

- Fainting
- Severe pains in the chest
- Shortness of breath
- Unexplained high blood pressure.

The initial diagnosis of CoA is often made by the infant or child's pediatrician, but in most cases the child will be referred to a pediatric cardiologist (heart specialist) for further evaluation. Approximately half of all infants with coarctation of the aorta are diagnosed within the first two months of life; however, the diagnosis is often missed during the first year. One study found that the average age of children referred to a pediatric cardiologist for treatment of CoA was 5 years. Frequently, there are other congenital cardiac complications present. The most common defects associated with coarctation of the aorta are **patent ductus arteriosus** (a ductus arteriosus that fails to close) and **ventricular septal defect** (VSD). In general, the younger the infant at the time of diagnosis, the greater the risk that he or she has other heart defects. Female infants with **Turner syndrome** have a 10% rate of also having coarctation. There is evidence that some cases of coarctation may be inherited.

Examination

Abnormal blood pressure readings can be detected during a **physical examination** in the doctor's office, as can abnormal heart rhythms. Infants with CoA usually have an abnormal "gallop" heart rhythm and may also have **heart murmurs**. Sometimes excessive arterial pulses can be seen in the carotid and suprasternal notch arteries, indicating increased pressure in these arteries, while the femoral pulse is weak or cannot be detected. The systolic pressure is higher in the arms than in the legs. Similar symptoms are seen in older children and adults. A 10 mm Hg (mercury) pressure difference between the upper and lower extremities is diagnostic for coarctation of the aorta. For some patients, the systolic pressure difference is observed only during **exercise**. Infants frequently have an abnormal electrocardiogram (ECG) that indicates that the right or both ventricles are enlarged, while in older children the ECG may be normal or show that the left ventricle is enlarged.

KEY TERMS

Anastomosis—A type of surgical procedure in which the surgeon joins together two parts of a hollow organ (such as a blood vessel or portion of the intestine) after a diseased or damaged section has been removed.

Aorta—The largest artery in the body, arising from the left ventricle (lower chamber) of the heart and extending down into the abdomen.

Coarctation—The medical term for a constriction or narrowing.

Congenital—Present at birth.

Ductus arteriosus—A blood vessel in the human fetus that connects the aortic arch to the pulmonary artery before birth and normally closes shortly after birth in healthy newborns.

Dyspnea—Difficulty in breathing. Usually associated with heart or lung diseases.

Electrocardiogram—A graph of the heart's beating produced by an instrument that detects the electrical signals made by the heart.

Gallop rhythm—An abnormal heart rhythm in which the doctor can hear three (sometimes four) sounds instead of the usual two, resembling the rhythm of a horse's gallop.

Hypertension—High blood pressure.

Notching—A deformity of the surface of the ribs that is often associated with coarctation of the aorta.

Turner syndrome—A genetic disorder that affects only females, in which one of the two X chromosomes that determine female sex is missing or otherwise abnormal.

Ventricular septal defect (VSD)—A defect or opening in the ventricular septum, the wall of tissue that separates the two lower chambers of the heart.

Tests

The doctor may also order imaging tests to evaluate any structural abnormalities in the heart and aorta. Enlargement of the heart can be seen in x rays. The coarctation may also be detected in echocardiographic examination or **magnetic resonance imaging** (MRI).

Procedures

In some cases the doctor may recommend **cardiac catheterization**. This is a procedure in which a long thin flexible tube called a catheter is threaded upward through an artery or vein in the leg until it reaches the heart. A dye is injected into the catheter in order to make the abnormalities in the aorta visible on x ray. Cardiac catheterization helps doctors evaluate the location and severity of the CoA.

Treatment

Drugs can be used to treat hypertension and **heart failure** while the patient is being evaluated for surgery. Surgery is recommended for infants with other associated cardiac defects and for those infants not responding to drug therapy. Surgery is indicated for infants that don't require immediate surgery, but who develop severe hypertension during the first several months of life. Patients are advised to avoid vigorous exercise prior to surgical correction of the coarctation. Recoarctation can occur in some patients even if they have had surgery; however, recoarctation can also be corrected by surgery.

Surgery

The first successful surgical correction of CoA was performed by a Swedish surgeon named Clarence Crafoord (1899–1983) in 1944. There are four major types of open-heart procedures used to repair CoAs in children:

- Resection and anastomosis. The surgeon removes the narrowed section of the aorta and reconnects the two ends of the blood vessel.
- Patch aortoplasty. The surgeon cuts across the narrowed section of the aorta and attaches a patch of synthetic material to widen the blood vessel.
- Flap angioplasty. The surgeon removes a portion of the left subclavian artery (the artery that carries blood to the left arm) and uses it to widen the narrowed portion of the aorta.
- Bypass graft. The surgeon inserts a plastic tube called a graft between the normal portions of the aorta, bypassing the coarctation.

Drugs

Medication cannot be used to treat CoA, but it can be used to control the patient's blood pressure

WWW.BOOKBAZ.IR

before surgery. Some people may also have to take blood pressure drugs after corrective surgery.

Infants with severe CoA may be given a drug called prostaglandin E to keep the ductus arteriosus open. The open ductus arteriosus will act like a bypass around the coarctation until the CoA can be repaired surgically.

Prognosis

Approximately half of all infants diagnosed with coarctation of the aorta have no other cardiac defects and will respond well to medical management. Most of these children will eventually outgrow the condition after several years of life. Although their hypertension may increase for several months early in life, it will eventually decrease as the circulatory system develops.

The average life span of adults who have untreated coarctation of the aorta is 34 years of age; 90% of such untreated patients die by age 50. The most common complications for children who have not had surgery are hypertension, aortic rupture, intracranial bleeding, **congestive heart failure**, and kidney or liver failure. Women who have an uncorrected coarctation of the aorta have a mortality rate of 10% during **pregnancy** and a 90% rate of complications.

Prevention

There is no known way to prevent coarctation of the aorta because the condition is present at birth in most cases. However, prompt evaluation of children with known heart defects or Turner syndrome for CoA can help in preventing complications of the condition. Surgeons recommend correcting the defect before age 10 if possible in order to prevent death in early adulthood; if coarctation is repaired before the age of 14 years, the 20-year survival rate is 91%. If the coarctation is repaired after age 14, the 20-year survival rate drops to 79%.

REVISED BY REBECCA J. FREY, PhD

Cocaine and related disorders

Definition

Cocaine is extracted from the coca plant, which grows in Central and South America. The substance is processed into many forms for use as an illegal drug of abuse. Cocaine is dangerously addictive, and users of the drug experience a "high"—a feeling of euphoria or intense happiness, along with hypervigilance, increased sensitivity, irritability or anger, impaired judgment, and **anxiety**.

Forms of the drug

In its most common form, cocaine is a whitish crystalline powder that produces feelings of euphoria when ingested. In powder form, cocaine is known by such street names as "coke," "blow," "C," "flake," "snow" and "toot." It is most commonly inhaled or snorted. It may also be dissolved in water and injected.

Crack is a form of cocaine that can be smoked and that produces an immediate, more intense, and more short-lived high. It comes in off-white chunks or chips called "rocks."

In addition to their stand-alone use, both cocaine and crack are often mixed with other substances. Cocaine may be mixed with methcathinone to create a "wildcat." Cigars may be hollowed out and filled with a mixture of crack and **marijuana**. Either cocaine or crack used in conjunction with heroin is called a "speedball." Cocaine used together with alcohol represents the most common fatal two-drug combination.

Demographics

The patterns of cocaine abuse in the United States have changed much over the past thirty years. They have been changing in other parts of the world as well, including South America and Western Europe. In the United States, several studies have attempted to track drug abuse in many different populations. The studies include: the Monitoring the Future Study (MTF); the National Household Survey on Drug Abuse (NHSDA); the Drug Abuse Warning Network (DAWN), which gets reports from emergency rooms and medical examiners' offices on drug-related cases and deaths; and Arrestee Drug Abuse Monitoring (ADAM), which gets information on urine samples obtained from people who have been arrested.

In the annual MTF study, cocaine use among high-school seniors had declined from 13.1% in 1985 to 3.1% in 1992—the lowest it had been since 1975, when the survey was first implemented. The rate of cocaine use began to rise again and peaked at 5.5% in 1997. The NHSDA found that the levels of cocaine use declined over the same time period. The decline in the rates has been thought to be due in part to education about the risks of cocaine abuse.

The incidence of new crack cocaine users has also decreased. There was a minimal decline in the numbers of excessive cocaine users between the years 1985 and 1997. The Epidemiologic Catchment Area (ECA) studies done in the early 1980s combined cocaine dependence with cocaine abuse and found that one-month to six-month prevalence rates for cocaine abuse and dependence were low or could not be measured. The lifetime rate of cocaine abuse was 0.2%.

A 1997 study from The National Institute on Drug Abuse indicates that among outpatients who abuse substances, 55% abuse cocaine.

Cocaine abuse affects both genders and many different populations across the United States. Males are one-and-a-half to two times more likely to abuse cocaine than females. Cocaine began as a drug of the upper classes in the 1970s; now the socioeconomic status of cocaine users has shifted. Cocaine is more likely to be abused by the economically disadvantaged because it is easy for them to get, and it is inexpensive ($10 for a small bag of crack cocaine). These factors have led to increased violence (people who are cocaine dependent may become involved in illegal activity, such as drug dealing, in order to acquire funds for their habit) and higher rates of acquired immune deficiency (**AIDS**) among disadvantaged populations.

A National Survey on Drug Use and Health (NSDUH) survey reports that in 2009, 4.8 million Americans age 12 and older had abused cocaine in any form. Adults 18 to 25 years of age have a higher rate of cocaine use than any other age group.

Description

Cocaine-related disorders form a very broad topic. According to the mental health clinician's handbook, *Diagnostic and Statistical Manual of Mental Disorders*,

WWW.BOOKBAZ.IR

fourth edition, text revised (also known as the *DSM-IV-TR*), the broad category of cocaine-related disorders can be subdivided into two categories: cocaine use disorders and cocaine-induced disorders. Cocaine use disorders include cocaine dependence and cocaine abuse. Cocaine-induced disorders include:

- cocaine intoxication
- cocaine withdrawal
- cocaine intoxication delirium
- cocaine-induced psychotic disorder, with delusions
- cocaine-induced psychotic disorder, with hallucinations
- cocaine-induced mood disorder
- cocaine-induced anxiety disorder
- cocaine-induced sexual dysfunction
- cocaine-induced sleep disorder
- cocaine-related disorder not otherwise specified

The fifth edition of the *DSM,* also known as the *DSM-5* is due for publication in 2013. This edition may include proposed changes and revisions to some current diagnostic criteria for psychiatric diagnoses, including combining "Substance Abuse," and "Dependence," into a single disorder, thus modifying "Cocaine Abuse," and "Cocaine Dependence," to a title of "Cocaine Use Disorder."

Cocaine use disorders

COCAINE ABUSE. For the cocaine abuser, the use of the substance leads to maladaptive behavior over a 12-month period. The person may fail to meet responsibilities at school, work, or home. The cocaine abuse impairs the affected person's judgment, and he or she puts himself or herself in physical danger to use the substance. For example, the individual may use cocaine in an unsafe environment. The person who abuses cocaine may be arrested or charged with possession of the substance, yet continue to use cocaine despite all of the personal and legal problems that may result.

COCAINE DEPENDENCE. Cocaine dependence is even more serious than cocaine abuse. Dependence is a maladaptive behavior that, over a three-month period, has caused the affected individual to experience tolerance for, and withdrawal symptoms from, cocaine. Tolerance is the need to increase the amount of cocaine intake to achieve the same desired effect. In other words, someone who is dependent on cocaine needs more cocaine to produce the same "high" that a lesser amount produced in the past. The dependent person also experiences cocaine withdrawal. Withdrawal symptoms develop within hours or days after cocaine use that has been heavy and prolonged and then abruptly stopped. The symptoms include irritable mood and two or more of the following symptoms: **fatigue**, nightmares, difficulty sleeping or too much sleep, elevated appetite, agitation (restlessness), or slowed physical movements. The onset of withdrawal symptoms can cause a person to use more cocaine to avoid these painful and uncomfortable symptoms. The dependent person uses larger amounts of cocaine for longer periods of time than intended. He or she cannot cut back on the use of the substance, often has a difficult time resisting cocaine when it is available, and may abandon work or school to spend more time acquiring and planning to acquire more cocaine. The individual continues to use cocaine despite the negative effects it has on family life, work, and school.

Cocaine-induced disorders

COCAINE INTOXICATION. Cocaine intoxication occurs after recent cocaine use. The person experiences a feeling of intense happiness, hypervigilance, increased sensitivity, irritability or anger, with impaired judgement, and anxiety. The intoxication impairs the person's ability to function at work or school or in social situations. Two or more of the following symptoms are present immediately after the use of cocaine:

- enlarged pupils
- elevated heart rate
- elevated or lowered blood pressure
- chills and increased sweating
- nausea or vomiting
- weight loss
- agitation or slowed movements
- weak muscles
- chest pain
- coma
- confusion
- irregular heartbeat
- depressed respiration
- seizures
- odd postures
- odd movements

COCAINE WITHDRAWAL. Withdrawal symptoms develop within hours or days after cocaine use that has been heavy and prolonged and then abruptly stopped. The symptoms include irritable mood and two or more of the following symptoms: fatigue, nightmares, difficulty sleeping or too much sleep, elevated appetite, agitation (restlessness), or slowed physical movements.

COCAINE-INDUCED DELIRIUM. According to the *DSM-IV-TR*, several criteria must be met in order for a health care professional to establish the diagnosis of cocaine-induced **delirium**. Patients have a disturbance of their level of consciousness or awareness, evidenced by drowsiness or an inability to concentrate or pay attention. Patients also experience a change in their cognition (ability to think) evidenced by a deficit in their language or their memory. For example, these patients may forget where they have placed an item, or their speech may be confusing. These symptoms have rapid onset within hours or days of using cocaine, and the symptoms fluctuate throughout the course of the day. These findings cannot be explained by **dementia** (state of impaired thought processes and memory that can be caused by various diseases and conditions), and the doctor must not be able to recognize a physical reason that can account for the symptoms other than cocaine intoxication.

COCAINE-INDUCED PSYCHOTIC DISORDER, WITH DELUSIONS. The person with this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience **delusions** (beliefs that the person continues to maintain, despite evidence to the contrary). In order for this state to be considered cocaine-induced psychotic disorder, these symptoms cannot be due to another condition or substance.

COCAINE-INDUCED PSYCHOTIC DISORDER, WITH HALLUCINATIONS. This condition is the same as cocaine-induced psychotic disorder with delusions, except that this affected individual experiences **hallucinations** instead of delusions. Hallucinations can be described as hearing and seeing things that are not real.

COCAINE-INDUCED MOOD DISORDER. The person with this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience depressed, elevated, or irritable mood with apathy (lack of empathy for others, and lack of showing a broad range of appropriate emotions).

COCAINE-INDUCED ANXIETY DISORDER. The person with this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience anxiety, panic attacks, obsessions, or compulsions. Panic attacks are discrete episodes of intense anxiety. Persons affected with panic attacks may experience accelerated heart rate, shaking or trembling, sweating, **shortness of breath**, or fear of going crazy or losing control, as well as other symptoms. An obsession is an unwelcome, uncontrollable, persistent idea, thought, image, or emotion that a person cannot help thinking even though it creates significant distress or anxiety. A compulsion is a repetitive, excessive, meaningless activity or mental exercise which a person performs in an attempt to avoid distress or worry.

COCAINE-INDUCED SEXUAL DYSFUNCTION. The person with this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience sexual difficulties, and these difficulties are deemed by the clinician to be due directly to the cocaine use. Substance-induced sexual difficulties can range from impaired desire, impaired arousal, impaired orgasm, or sexual **pain**.

COCAINE-INDUCED SLEEP DISORDER. This disorder is characterized by difficulty sleeping (**insomnia**) during intoxication or increased sleep duration when patients are in withdrawal.

COCAINE-RELATED DISORDER NOT OTHERWISE SPECIFIED. This classification is reserved for clinicians to use when a cocaine disorder that the clinician sees does not fit into any of the above categories.

Causes and symptoms

Causes

BIOCHEMICAL/PHYSIOLOGICAL CAUSES. Twin studies have demonstrated that there is a higher rate of cocaine abuse in identical twins as compared to fraternal twins. This indicates that genetic factors contribute to the development of cocaine abuse. This finding also indicates, however, that unique environmental factors contribute to the development of cocaine abuse as well. (If genes alone determined who would develop cocaine dependence, 100% of the identical twins with the predisposing genes would develop the disorder. However, because the results show only a relationship, or a correlation, between genetics and cocaine use among twins, these results indicate that other factors must be at work as well.) Studies have also shown that disorders like **attention deficit hyperactivity disorder (ADHD)**, **conduct disorder**, and antisocial personality disorder all have genetic components, and since patients who abuse cocaine have a high incidence of these diagnoses, they may also be genetically predisposed to abusing cocaine.

REINFORCEMENT. Learning and conditioning also play a unique role in the perpetuation of cocaine abuse. Each inhalation and injection of cocaine causes pleasurable feelings that reinforce the drug-taking procedure. In addition, the patient's environment plays a role in cueing and reinforcing the experience

WWW.BOOKBAZ.IR

in the patient's mind. The association between cocaine and environment is so strong that many people recovering from cocaine **addiction** report that being in an area where they used drugs brings back memories of the experience and makes them crave drugs. Specific areas of the brain are thought to be involved in cocaine craving, including the amygdala (a part of the brain that controls aggression and emotional reactivity) and the prefrontal cortex (a part of the brain that regulates anger, aggression, and the brain's assessment of fear, threats, and danger).

Symptoms

The following list is a summary of the acute (short-term) physical and psychological effects of cocaine on the body:

- blood vessels constrict
- elevated heart rate
- elevated blood pressure
- a feeling of intense happiness
- elevated energy level
- a state of increased alertness and sensory sensitivity
- elevated anxiety
- panic attacks
- elevated self-esteem
- diminished appetite
- spontaneous ejaculation and heightened sexual arousal
- psychosis (loss of contact with reality)

The following list is a summary of the chronic (long-term) physical and psychological effects of cocaine on the body:

- depressed mood
- irritability
- physical agitation
- decreased motivation
- difficulty sleeping
- hypervigilance
- elevated anxiety
- panic attacks
- hallucinations
- psychosis

Diagnosis

If a mental health clinician suspects cocaine use, he or she may ask the patient specifically about swallowing, injecting, or **smoking** the substance. Urine and blood testing will also be conducted to determine the presence of the substance. Doctors may talk to friends or relatives concerning the patient's drug use, especially for cases in which the physician suspects that the patient is not being entirely honest about substance use. The clinician may also investigate a patient's legal history for drug arrests that may give clues to periods of substance abuse to which the patient will not admit.

KEY TERMS

Anxiety—Can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

Depression—A mental state characterized by feelings of sadness, despair, and discouragement.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses and helps to regulate movement and emotions.

Hallucinations—To hear, see, or otherwise sense things that are not real. Hallucinations can result from nervous system abnormalities, mental disorders, or the use of certain drugs.

Panic attack—A period of intense fear or discomfort with a feeling of doom and a desire to escape. The person may shake, sweat, be short of breath, and experience chest pain.

Differential diagnosis

Differential diagnosis is the process of distinguishing one condition from other, similar conditions. The cocaine abuse disorder is easily confused with other substance abuse disorders and various forms of mental illness.

The symptoms of cocaine intoxication, such as increased talkativeness, poor sleep, and the intense feelings of happiness, are similar to the symptoms for **bipolar disorder**, so the urine toxification screening test may play a key role in the diagnosis. Patients with cocaine intoxication with hallucinations and delusions can be mistaken for schizophrenic patients instead, further emphasizing the importance of the urine and blood screens. As part of establishing the diagnosis, the physician must also rule out PCP (phencyclidine) intoxication and Cushing's disease (an endocrine disorder of excessive cortisol production). Withdrawal symptoms are similar to those of the patient with major depression. For this reason, the clinician may ask the patient about his or her mood during times of abstinence from drug use to discern

whether any true **mood disorders** are present. If cocaine use is causing depression, the depression should resolve within a couple of weeks of stopping drug use.

Laboratory testing

The breakdown products of cocaine remain in the urine. The length of time that they remain depends on the dose of cocaine, but most doses would not remain in the urine longer than a few days. Cocaine can also be found in other bodily fluids such as blood, saliva, sweat, and hair, and these provide better estimates as to recent cocaine use. The hair can hold evidence that a patient has been using drugs for weeks to months. **Positron emission tomography** (PET) and single-photon emission computed tomography (SPECT) are different kinds of imaging studies. Both kinds of scans look at the amount of blood that is flowing to the brain. When these images are taken of the brains of people who abuse cocaine, the resulting scans can reveal abnormalities in certain sections of the brain. The brains of people addicted to cocaine shrink, or atrophy.

Neuropsychological assessment

Neuropsychological testing is also an important tool for examining the effects of toxic substances on brain functioning. Some physicians may use neuropsychological assessments to reveal patients' cognitive and physical impairment after cocaine use. Neuropsychological testing assesses brain functioning through structured and systematic behavioral observation. Neuropsychological tests are designed to examine a variety of cognitive abilities, including speed of information processing, attention, memory, and language. An example of a task that a physician might ask the patient to complete as part of a neuropsychological examination is to name as many words beginning with a particular letter as the patient can in one minute. Patients who abuse cocaine often have difficulty completing tasks, such as the one described, that require concentration and memory.

Treatment

Psychological and social interventions

TREATMENT SETTINGS. Not all patients who abuse cocaine need to resort to long-term treatment. Treatment length varies with the degree that a person is dependent on the substance. If the patient has other psychiatric conditions, such as major depression or **schizophrenia**, or has significant medical complications of cocaine abuse, then he or she is more likely to require higher-intensity treatment. Residential programs or therapeutic communities may be helpful, particularly in more severe cases. Patients typically spend six to 12 months in such programs, which may also include vocational training and other features. The availability of such treatment, as well as medical insurance's ability to cover treatment, are all issues that affect the patient's access to treatment.

PSYCHOTHERAPY. A wide range of behavioral interventions have been successfully used to treat cocaine addiction. The approach used must be tailored to the specific needs of each individual patient, however.

Contingency management rewards drug abstinence (confirmed by urine testing) with points or vouchers that patients can exchange for such things as an evening out or membership in a gym. **Cognitive-behavioral therapy** helps users learn to recognize and avoid situations most likely to lead to cocaine use and to develop healthier ways to cope with stressful situations.

Supportive therapy helps patients to modify their behavior by preventing relapse by taking actions such as staying away from drug-using friends and from neighborhoods or situations where cocaine is abundant.

Self-help groups like Narcotics Anonymous (NA) or Cocaine Anonymous (CA) are helpful for many recovering substance abusers. CA is a twelve-step program for cocaine abusers, modeled after Alcoholics Anonymous (AA). Support groups and **group therapy** led by a therapist can be helpful because other addicts can share coping and relapse-prevention strategies. The group's support can help patients face devastating changes and life issues. Some experts recommend that patients be cocaine-free for at least two weeks before participating in a group, but other experts argue that a two-week waiting period is unnecessary and counterproductive. Group counseling sessions led by drug counselors who are in recovery themselves are also useful for some people overcoming their addictions. These group counseling sessions differ from group therapy in that the people in a counseling group are constantly changing.

The National Institute of Drug Abuse conducted a study comparing different forms of **psychotherapy**: patients who had both group drug counseling and individual drug counseling had improved outcomes. Patients who had cognitive-behavioral therapy stayed in treatment longer.

WWW.BOOKBAZ.IR

Medications

Many medications—greater than twenty—have been tested, but none has been found to reduce the intensity of withdrawal. Dopamine agonists like amantadine and bromocriptine and tricyclic antidepressants such as desipramine have failed in studies to help treat symptoms of cocaine withdrawal or intoxication.

Alternatives

Alternative techniques, such as **acupuncture**, EEG **biofeedback**, and visualization, may be useful in treating addiction when combined with conventional treatment approaches.

Prognosis

Not all cocaine abusers become dependent on the drug. However, even someone who only uses occasionally can experience the harmful effects (interpersonal relationship conflicts, work or school difficulties) of using cocaine, and even occasional use is enough to addict. In the course of a person's battle with cocaine abuse, he or she may vary the forms of the drug that he or she uses. A person may use the inhaled form at one time and the injected form at another, for example.

Many studies of short-term outpatient treatment over a six-month to two-year period indicate that people addicted to cocaine have a better chance of recovering than people who are addicted to heroin. A study of veterans who participated in an inpatient or day hospital treatment program that lasted 28 days revealed that about 60% of people who were abstinent at four months were able to maintain their abstinence at seven months.

Having a good social support network greatly improves the prognosis for recovery from cocaine abuse and dependence.

Prevention

Efforts to prevent cocaine abuse, as well as any substance abuse, begin with prevention programs that are based in schools or in the workplace, heath care clinics, criminal justice systems, and public housing. Programs such as Students Taught Awareness (STAR) are cost-effective and have reduced the rates of substance abuse in the schools. These school-based programs also foster parental involvement and education about substance abuse issues. The juvenile justice system also implements drug-prevention programs. Even many workplaces provide drug screening and treatment and counseling for those who test positive. Employers may also provide workshops on substance abuse prevention. The United States Department of Housing and Urban Development (HUD) also sponsors drug-prevention programs.

REVISED BY LAURA JEAN CATALDO, RN, EdD

Coccidioidomycosis

Definition

Coccidioidomycosis is an infection caused by inhaling the microscopic spores of the fungus *Coccidioides immitis*. Spores are the tiny, thick-walled structures that fungi use to reproduce. Coccidioidomycosis exists in three forms. The acute form produces flu-like symptoms. The chronic form can develop as many as 20 years after initial infection and, in the lungs, can produce inflamed, injured areas that can fill with pus (abscesses). Disseminated coccidioidomycosis describes the type of coccidioidomycosis that spreads throughout the body affecting many organ systems and is often fatal.

Description

Coccidioidomycosis is an airborne infection. The fungus that causes the disease is found in the dry desert soil of the southwestern United States, Mexico, and Central and South America. Coccidioidomycosis is sometimes called San Joaquin **fever**, valley fever, or desert fever because of its prevalence in the farming valleys of California. Although commonly acquired, overt coccidioidomycosis is a rare disease. Chronic infections occur in only one out of every 100,000 people.

Although anyone can get coccidioidomycosis, farm laborers, construction workers, and archaeologists who work where it is dusty are at greater risk to become infected. People of any age can get coccidioidomycosis, but the disease most commonly occurs in the 25–55 age group. In its acute form, coccidioidomycosis infects men and women equally.

Chronic and disseminated forms of coccidioidomycosis occur more frequently in men and pregnant women. Although it is not clear why, people of color are 10–20 times more likely to develop the disseminated form of the disease than caucasians. People who have a weakened immune system (immunocompromised), either from diseases such as **AIDS** or leukemia, or as the result of medications that suppressed the immune system (**corticosteroids**, **chemotherapy**), are more likely to develop disseminated coccidioidomycosis.

Causes and symptoms

When the spores of *C. immitis* are inhaled, they can become lodged in the lungs, divide, and cause localized inflammation. This is known as acute or primary coccidioidomycosis. The disease is not spread from one person to another. Approximately 60% of people who are infected exhibit no symptoms (asymptomatic). In the other 40%, symptoms appear 10–30 days after exposure. These symptoms include a fever which can reach 104°F (39.5°C), dry **cough**, chest pains, joint and muscle aches, **headache**, and weight loss. About two weeks after the start of the fever, some people develop a painful red rash or lumps on the lower legs. Symptoms usually disappear without treatment in about one month. People who have been infected gain partial immunity to reinfection.

The chronic form of coccidioidomycosis normally occurs after a long latent period of 20 or more years during which the patient experiences no symptoms of the disease. In the chronic phase, coccidioidomycosis causes lung abscesses that rupture, spilling pus and fluid into the lungs, and causing serious damage to the lungs. The patient experiences difficulty breathing and has a fever, chest **pain**, and other signs of **pneumonia**. Medical treatment is essential for recovery.

In its disseminated form, coccidioidomycosis spreads to other parts of the body including the liver, bones, skin, brain, heart, and lining around the heart (pericardium). Symptoms include fever, joint pain, loss of appetite, weight loss, night sweats, **skin lesions**, and difficulty breathing. Also, in 30–50% of patients with disseminated coccidioidomycosis, the tissue coverings of the brain and spinal cord become inflamed (**meningitis**).

Diagnosis

Many cases of coccidioidomycosis go undiagnosed because the symptoms resemble those of common viral diseases. However, a skin test similar to that for **tuberculosis** will determine whether a person has been infected. The test is simple and accurate, but it

WWW.BOOKBAZ.IR

KEY TERMS

Abscess—An area of inflamed and injured body tissue that fills with pus.

Acidophilus—The bacteria *Lactobacillus acidophilus* that usually found in yogurt.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—A foreign protein to which the body reacts by making antibodies.

Asymptomatic—Persons who carry a disease but who do not exhibit symptoms of the disease are said to be asymptomatic.

Bifidobacteria—A group of bacteria normally present in the intestine. Commercial supplements containing these bacteria are available.

Corticosteroids—A group of hormones produced naturally by the adrenal gland or manufactured synthetically. They are often used to treat inflammation. Examples include cortisone and prednisone.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

Meningitis—An inflammation of the membranes surrounding the brain or spinal cord.

Pericardium—The tissue sac around the heart.

does not indicate whether the disease was limited to its acute form or if it has progressed to its chronic form.

Diagnosis of chronic or disseminated coccidioidomycosis is made by culturing a sample of sputum or other body fluids in the laboratory to isolate the fungus. A blood serum test is used to detect the presence of an antibody produced in response to *C. immitis* infection. Chest x rays are often used to assess lung damage, but alone cannot lead to a definitive diagnosis of coccidioidomycosis because other diseases can produce similar results on the x ray.

Treatment

In most cases of acute coccidioidomycosis, the body's own immune system is adequate to bring about recovery without medical intervention. Fever and pain can be treated with non-prescription drugs.

Chronic and disseminated coccidioidomycosis, however, are serious diseases that require treatment with prescription drugs. Patients with intact immune systems who develop chronic coccidiodomycosis are treated with the drug ketoconazole (Nizoral) or amphotericin B (Fungizone). Patients with suppressed immune systems are treated with amphotericin B (Fungizone). Amphotericin B is a powerful fungistatic drug with potentially toxic side effects. As a result, hospitalization is required in order to monitor patients. The patient may also receive other drugs to minimize the side effects of the amphotericin B.

Patients with AIDS must continue to take itraconazole (Sporonox) or fluconazole (Diflucan) orally or receive weekly intravenous doses of amphotericin B for the rest of their lives in order to prevent a relapse. Because of the high cost of fluconazole, Pfizer, the manufacturer of the drug, has established a financial assistance plan to make the drug available at lower cost to those who meet certain criteria. Patients needing this drug should ask their doctors about this program.

Alternatives

Alternative treatment for **fungal infections** focuses on creating an internal environment where the fungus cannot survive. This is accomplished by eating a diet low in dairy products, sugars, including honey and fruit juice, and foods like beer that contain yeast. This is complemented by a diet consisting, in large part, of uncooked and unprocessed foods. Supplements of **vitamins** C, E, A-plus, and B complex may also be useful. *Lactobacillus acidophilus* and *Bifidobacterium* will replenish the good bacteria in the intestines. Antifungal herbs, like garlic (*Allium sativum*), can be consumed in relatively large does and for an extended period of time in order to increase effectiveness.

Prognosis

Most people who are infected with coccidiodomycosis only suffer from the mild, acute form of the disease and recover without further complications. Patients who suffer from chronic coccidiodomycosis and who have no underlying lung or immune system diseases also stand a good change of recovery, although they must be alert to a relapse.

The picture for patients with the disseminated form of the disease, many of whom have AIDS, is less positive. Untreated disseminated coccidiodomycosis is almost always fatal within a short time. With treatment, chance of survival increases, but the death rate remains high when meningitis or diffuse lung

(pulmonary) disease is present. AIDS patients must constantly guard against relapse.

Prevention

Because the fungus that causes coccidioidomycosis is airborne and microscopic, the only method of prevention is to avoid visiting areas where it is found in the soil. Unfortunately, for many people this is impractical. Maintaining general good health and avoiding HIV infection will limit coccidioidomycosis to the acute and relatively mild form in most people.

Tish Davidson, A.M.

Coccyx injuries

Definition

The coccyx—or tailbone—is the last bone of the vertebral column, and usually consists of three to five fused vertebrae that connect with the sacrum, a part of the pelvis.

Description

The coccyx consists of fused vertebrae, which are not flexible like the other vertebrae of the vertebral column which are all interspaced by intervertebral disks and joined together by elastic ligaments. Since the spinal cord ends just before the coccyx begins, coccygeal vertebrae also lack a central foramen (hole). In the coccyx, the vertebrae generally fuse together in early adulthood and may also fuse with the sacrum, the bone located between the fifth lumbar vertebra and the coccyx, as a person ages. In males, the coccyx curves downward, and in females, it is straighter to allow a baby to pass through the birth canal without impediment.

Pain in or around the coccyx is called coccydynia or coccygodynia. Coccydynia presents a range of symptoms associated to a variety of underlying causes and conditions.

Causes and symptoms

Causes

Coccydynia can be caused by a number of factors. Usually, patients report pain after a fall onto their buttocks, as occurs when going down stairs or while skating. Others have pain during **pregnancy** or after **childbirth**. Some experience repetitive strain from rowing or cycling, and some cite anal intercourse as the cause of pain. In many cases, pain derives from a malformation of the coccyx itself. Sometimes bony spurs appear on the coccyx, but only seem to be painful in thin patients who do not have the padding to protect the region from the spur.

Other causes of coccydynia include cancer or damage to the sacrum that generates referred pain, meaning pain that appears in one region but originates from another. Muscle strain or tension, pinched nerves or damaged nerves, or dislocation of the coccyx due to gross **obesity** are other causes.

Symptoms

The most common symptom of coccydynia, irrespective of the cause of the condition, is pain when sitting, or when rising from a sitting position. If the condition lasts long enough, the patient may even experience pain when standing or lying down. Sometimes, numbness occurs in the lower part of the spine. Some patients will experience pain during bowel movements, sexual intercourse, or menstruation.

Secondary symptoms include back pain from sitting in odd positions in order to relieve pain, and painful feet from standing too much, because patients avoid sitting. Sometimes the entire buttocks experience pain. Rarely, exhaustion, depression, and lack of sleep may occur.

Diagnosis

Diagnosis of fracture is usually made by inserting a gloved finger in the rectum and pressing on the coccyx. X rays and **magnetic resonance imaging** (MRI) are also often used. Since coccyx pain may be the result of

WWW.BOOKBAZ.IR

KEY TERMS

Coccydynia—Also called coccygodynia. Pain in or around the coccyx.

Coccyx—The last bone of the spinal column, consisting of three to five fused vertebrae that connect with the sacrum, a part of the pelvis.

Foramen—A small opening, perforation, or orifice.

Magnetic resonance imaging (MRI)—An imaging technique that produces pictures of the inside of the body.

Sacrum—The triangle-shaped bone located between the fifth lumbar vertebra and the coccyx that consists of five vertebrae fused together. The sacrum joins on each side with the bones of the pelvis.

Spinal cord—Elongated nerve bundles that lie in the vertebral canal and from which the spinal nerves emerge.

Vertebrae—Bones in the cervical, thoracic, and lumbar regions of the body that make up the vertebral column. Vertebrae have a central foramen (hole), and their superposition makes up the vertebral canal that encloses the spinal cord.

Vertebral column—The vertebral column, also called the spinal column or spine, consists of a series of vertebrae connected by ligaments. It provides a supporting axis for the body and protects the spinal cord. The vertebral column consists of seven cervical vertebrae in the neck, followed by 12 thoracic vertebrae that connect to the ribs, five lumbar vertebrae in the lower back, the sacrum, and the coccyx.

other factors like cancer, these must be ruled out through a variety of tests before treatment can begin.

Treatment

Treatment exists to either control the pain or eliminate the cause. Pain control may be dangerous if an underlying condition exists of which the pain is a warning sign. Nerve blocks and a variety of drugs are other options to control pain.

Elimination of the root cause of the pain is ideal. This is done through careful diagnosis and the application of manual treatments, corticosteroid injections into the coccyx vertebrae, or surgery. Injections into the fourth and fifth sacral nerves and coccygeal nerves often bring relief, but are considered more as a pain control measure than as curative treatment. Manual treatments have not been found to be effective. Surgery is a radical procedure whose indications are inconsistent and dependent on the subjectivity of the physician.

Prognosis

With current treatment, prognosis is good and patients usually are able to live pain free.

Prevention

There probably is no real prevention, except weight control. Some women may choose to give birth through caesarian section instead of vaginally after an episode of coccyx pain from a previous delivery.

Cochlear implants

Definition

A cochlear implant (CI) is a small, complex electronic device used to treat severe to profound **hearing loss**. It is surgically implanted underneath the skin behind the patient's ear to provide direct electrical stimulation to the auditory nerve in the inner ear. The CI provides the sense of sound to people, both children and adults, who are deaf or severely hard of hearing and in which **hearing aids** cannot help restore all or part of their hearing.

Purpose

A cochlear implant helps people who are deaf due to damage to the sensory hair cells within the cochlea, which is part of the inner ear. Such damage is called

A close-up view of a cochlear implant. *(Custom Medical Stock Photo, Inc.)*

sensorineural hearing loss because sounds are unable to reach the auditory nerve. Although a cochlear implant cannot restore hearing completely, it can provide sufficient hearing so these people can better understand the speech of themselves and others. It delivers useful auditory signals from the environment to the patient by electronically bypassing nonfunctional parts of the ear and directly stimulating the auditory nerve. Unlike a hearing aid, it does not merely amplify sound. Instead, an implant increases the amount of nervous response to sound. Although it does not restore normal hearing, the additional input provided by the implant often improves sound detection and increases speech understanding.

Description

Normal hearing occurs because sound travels from the outer ear into the ear canal and vibrates the eardrum. The vibration is carried through the middle ear by three small bones attached to the eardrum and on to a fluid-filled part of the inner ear called the cochlea. Movement in the cochlear fluid is transferred to hair fibers within the cochlea. The movement of these hair cells stimulates nerve cells called **ganglion** cells, which send an electrical current to the auditory nerve. In turn, the nerve carries the electrical current to the brain, where the electrical stimulation is recognized as sound.

A common cause of hearing loss is damage to the hair cells within the cochlea. This kind of deafness, called sensorineural deafness, can often be treated with cochlear implants. This is particularly true if damage to the hair cells is not accompanied by damage to the auditory nerve itself. It has been estimated that more than 200,000 individuals have received cochlear implants worldwide.

Cochlear implants consist of internal and external parts. The external parts include a microphone, a speech processor, and a transmitter. The internal parts include a receiver-stimulator and an electrode. Some models include a small headpiece that is worn just behind the ear and contains all the external parts, while other models also use body-worn modules that are placed in a shoulder pouch, in a pocket, or worn on a belt. The convenience of the all-in-one headpiece is balanced by shorter life for the batteries used in the smaller units, although systems using rechargeable batteries do solve some of these issues.

Within the headpiece, the microphone picks up sound in the environment. The speech processor converts these sounds into a digital signal. The content of the generated digital signal is determined by the programming of the processor and is complex. It includes information about the pitch, loudness, and timing of sound signals, and attempts to filter out extraneous noise. The transmitter converts the digital signals into FM radio signals (where FM is short for frequency modulation) and sends them through the skin to the internal parts of the implant. The transmitter and the internal parts are kept in correct alignment by using magnets present in both the internal and external parts of the device.

The internal parts are those that are surgically implanted into the patient. The receiver-stimulator is disk-shaped and is about the size of a quarter. It receives the digital signals from the transmitter and converts them into electrical signals. A wire connects the receiver to a group of electrodes that are threaded into the cochlea when the implant is placed. As many as 24 electrodes, depending on the type of the implant, stimulate the ganglion cells in the cochlea. These cells transmit the signals to the brain through the auditory nerve. The brain then interprets the signals as sound.

The sounds heard through an implant are different from the normal hearing sounds and have been described as artificial or robot-like. This is because the implant's handful of electrodes cannot hope to match the complexity of a person's 15,000 hair cells. However, as more electrodes are added, electrode placement issues are solved, and the software for the implant speech processor takes into account more and more aspects of sound, the perceived results are moving closer to how speech and other sounds are naturally perceived.

Despite the benefits that the implant appears to offer, some hearing specialists and members of the deaf community believe that the benefits may not outweigh the risks and limitations of the device. Because

WWW.BOOKBAZ.IR

the device must be surgically implanted, it carries some surgical risk. Manufacturers cannot promise how well a person will hear with an implant. Moreover, after getting an implant, some people say they feel alienated from the deaf community, while at the same time not feeling fully a part of the hearing world. The decision to undergo cochlear implant surgery is a complex one, and a person should take into account the risks and realistic rewards of the device.

Surgical procedure

The procedure can be performed on an outpatient basis for adult and adolescent patients. With children, it is often performed with a one-night stay in the hospital.

The internal parts of the implant are placed under the skin behind the patient's ear. The area is shaved, although newer procedures allow for sterilization of the hair in the area so less shaving has to occur. Once the sterile field is established, the surgeon makes a 2–3 in (5–7.6 cm) incision behind the ear and opens the mastoid bone (the ridge on the skull behind the ear) leading into the middle ear. A depression is made in the bone next to the opening to allow the receiver-stimulator to sit flush with the skull surface. After seating, the receiver-stimulator is held in place with a long-lasting suture.

The surgeon then goes through the opening in the mastoid bone to create a new opening in the cochlea for the implant electrodes. The electrode is then very slowly and carefully threaded through this new opening. The electrode structure itself is designed to align the electrodes as closely as possible to the ganglion cells, as this allows the electrical signals that function to be less powerful. Once in place, the device is tested to be certain it is working. If all is well, the surgeon then closes up the incision with absorbable sutures, so the area does not need to be revisited to remove the stitches.

The entire operation takes between one and two hours, although the procedure is more complex for younger patients due to the smaller size of their middle ear structures and tends to take longer.

Demographics

According to the U.S. Food and Drug Administration (FDA), about 58,000 adults and 38,000 children have received cochlear implants in the United States, as of December 2014. Worldwide, the FDA states that approximately 320,000 people have received cochlear implants.

Preparation

The cochlear implant team will help patients prepare for their surgery. In addition, each patient should bring a family member or friend to the surgical site in case help with communicating is needed, along with driving the patient home once the surgery is completed.

The surgical team will ask patients to stop **smoking** tobacco products such as cigarettes before the operation. Tobacco smoking increases the risk of infection after the procedure has been completed. If a general anesthetic is being administered, then a **fasting** period will be required before the procedure. Generally, this means that no food or drink can be consumed for about six hours before the start of the procedure.

Aftercare

For a short period of time after the surgery, a special bandage is worn on the head during sleep. After about one month, the surgical **wounds** heal. The patient then returns to the implant clinic to be fitted with the external parts of the device and to have it turned on and mapped. Mapping involves fine tuning the speech processor and setting levels of stimulation for each electrode, from soft to loud.

The patient is then trained in how to interpret the sounds heard through the device. The length of the training varies from days to years, depending on how well the person can interpret the sounds heard through the device.

Risks

As with all operations, there are risks with this surgery, including:

- infection at the incision site
- bleeding
- complications related to anesthesia
- transient dizziness
- facial paralysis (rarely)
- temporary taste disturbances
- additional hearing loss
- device failure

It should be noted that serious surgical complications have been observed in only about one in 10,000 procedures of this type.

Some long-term risks of the implant include the unknown effects of electrical stimulation on the nervous system. It is also possible to damage the implant's internal components by a blow to the head, which will render the device unworkable.

A further consideration is that the use of **magnetic resonance imaging** (MRI) for patients with cochlear implants is not recommended because of the magnets present in the devices. Several companies have developed implants that do not use magnets, or have altered the receiver-stimulator to make it easier to remove the magnets before testing. One fact that reduces the concern about MRI testing is that for many medical indications, MRI can be replaced with a computer assisted tomography (CAT) scan, which is not a problem for persons with cochlear implants.

Additionally, in July 2002, the U.S. Food and Drug Administration (FDA) issued a warning about a possible connection between increased incidence of **meningitis** and the presence of a cochlear implant. This warning included special vaccine recommendations for those with implants, as well as the voluntary removal from the market of certain devices. Specifically, those implants that included a positioner to hold the electrodes in place in the cochlea appear to be associated with an increased risk of the disease. As of 2014, it remained unclear whether there is a valid connection between the increased risk from meningitis and the presence of cochlear implants. Concerns should be directed to the surgical team and other medical professionals such as a trusted family doctor.

Results

Most profoundly deaf patients who receive an implant are able to discern medium and loud sounds, including speech, at comfortable listening levels. Many use sound clues from the implant, together with speech reading and other facial cues, to achieve understanding. Almost all adults improve their communication skills when combining the implant with speech reading (lip reading), and some can understand spoken words without speech reading. More than half of adults who lost hearing after they learned to speak can understand some speech without speech reading. Especially with the use of accessory devices, the great majority can utilize the telephone with their implants.

Children who were born deaf or who lost their hearing before they could speak have the most difficulty in learning to use the implant. Research suggests, however, that most of these children are able to learn spoken language and understand speech using the implant. In general, the earlier the implant occurs, the greater the chance of the implant providing sufficient sound input to provide speech understanding. As with the use of the telephone in adults, accessory devices such as special microphones often help the function of the implant in classroom settings.

KEY TERMS

Auditory nerve—The nerve that carries electrical signals from the cochlea to the brain.

Cochlea—The hearing part of the inner ear. This snail-shaped structure contains fluid and thousands of microscopic hair cells tuned to various frequencies.

Hair cells—Sensory receptors in the inner ear that transform sound vibrations into messages that travel to the brain.

Inner ear—The interior section of the ear, where sound vibrations and information about balance are translated into nerve impulses.

Middle ear—The small cavity between the eardrum and the oval window that houses the three tiny bones of hearing.

Sensorineural deafness—Hearing loss due to the inability to convert sound from vibration to electrical signals. Often involves defects in the function of cochlear hair cells.

Health care team roles

Cochlear implants are inserted during a surgery performed by a specialist in otolaryngology (ear, nose, and throat medicine). The surgery is performed in a larger hospital, usually on an outpatient basis, but sometimes with an overnight hospital stay.

REVISED BY WILLIAM A. ATKINS, BB, BS, MBA

Cognitive-behavioral therapy

Definition

Cognitive-behavioral therapy is an action-oriented form of psychosocial therapy that assumes that maladaptive, or faulty, thinking patterns cause maladaptive behavior and "negative" emotions. (Maladaptive behavior is behavior that is counter-productive or interferes with everyday living.) The treatment focuses on changing an individual's thoughts (cognitive patterns) in order to change his or her behavior and emotional state.

Purpose

Theoretically, cognitive-behavioral therapy can be employed in any situation in which there is a pattern of unwanted behavior accompanied by distress and impairment. It is a recommended treatment option for a number of mental disorders, including affective (mood) disorders, **personality disorders**, social phobia, **obsessive-compulsive disorder** (OCD), **eating disorders**, substance abuse, **anxiety** or **panic disorder**, **agoraphobia**, **post-traumatic stress disorder** (PTSD), and attention-deficit/hyperactivity disorder (**ADHD**). It is also frequently used as a tool to deal with chronic **pain** for patients with illnesses such as **rheumatoid arthritis**, back problems, and cancer. Patients with **sleep disorders** may also find cognitive-behavioral therapy a useful treatment for **insomnia**.

Precautions

Cognitive-behavioral therapy may not be suitable for some patients. Those who do not have a specific behavioral issue they wish to address and whose goals for therapy are to gain insight into the past may be better served by psychodynamic therapy. Patients must also be willing to take a very active role in the treatment process.

Cognitive-behavioral intervention may be inappropriate for some severely psychotic patients and for cognitively impaired patients (for example, patients with organic brain disease or a **traumatic brain injury**), depending on their level of functioning.

Description

Cognitive-behavioral therapy combines the individual goals of cognitive therapy and behavioral therapy.

Pioneered by psychologists Aaron Beck and Albert Ellis in the 1960s, cognitive therapy assumes that maladaptive behaviors and disturbed mood or emotions are the result of inappropriate or irrational thinking patterns, called *automatic thoughts*. Instead of reacting to the reality of a situation, an individual reacts to his or her own distorted viewpoint of the situation. For example, a person may conclude that he is "worthless" simply because he failed an exam or did not get a date. Cognitive therapists attempt to make their patients aware of these distorted thinking

patterns, or cognitive distortions, and change them (a process termed cognitive restructuring).

Behavioral therapy, or behavior modification, trains individuals to replace undesirable behaviors with healthier behavioral patterns. Unlike psychodynamic therapies, it does not focus on uncovering or understanding the unconscious motivations that may be behind the maladaptive behavior. In other words, strictly behavioral therapists do not try to find out why their patients behave the way they do, they just teach them to change the behavior.

Cognitive-behavioral therapy integrates the cognitive restructuring approach of cognitive therapy with the behavioral modification techniques of behavioral therapy. The therapist works with the patient to identify both the thoughts and the behaviors that are causing distress, and to change those thoughts in order to readjust the behavior. In some cases, the patient may have certain fundamental core beliefs, called schemas, which are flawed and require modification. For example, a patient with depression may be avoiding social contact with others, and suffering considerable emotional distress because of his **isolation**. When questioned why, the patient reveals to his therapist that he is afraid of rejection, of what others may do or say to him. Upon further exploration with his therapist, they discover that his real fear is not rejection, but the belief that he is hopelessly uninteresting and unlovable. His therapist then tests the reality of that assertion by having the patient name friends and family who love him and enjoy his company. By showing the patient that others value him, the therapist both exposes the irrationality of the patient's belief and provides him with a new model of thought to change his old behavior pattern. In this case, the person learns to think, "I am an interesting and lovable person; therefore I should not have difficulty making new friends in social situations." If enough "irrational cognitions" are changed, this patient may experience considerable relief from his depression.

A number of different techniques may be employed in cognitive-behavioral therapy to help patients uncover and examine their thoughts and change their behaviors. They include:

- Behavioral homework assignments. Cognitive-behavioral therapists frequently request that their patients complete homework assignments between therapy sessions. These may consist of real-life "behavioral experiments" where patients are encouraged to try out new responses to situations discussed in therapy sessions.
- Cognitive rehearsal. The patient imagines a difficult situation and the therapist guides him through the step-by-step process of facing and successfully dealing with it. The patient then works on practicing, or rehearsing, these steps mentally. Ideally, when the situation arises in real life, the patient will draw on the rehearsed behavior to address it.
- Journal. Patients are asked to keep a detailed diary recounting their thoughts, feelings, and actions when specific situations arise. The journal helps to make the patient aware of his or her maladaptive thoughts and to show their consequences on behavior. In later stages of therapy, it may serve to demonstrate and reinforce positive behaviors.
- Modeling. The therapist and patient engage in role-playing exercises in which the therapist acts out appropriate behaviors or responses to situations.
- Conditioning. The therapist uses reinforcement to encourage a particular behavior. For example, a child with ADHD gets a gold star every time he stays focused on tasks and accomplishes certain daily chores. The gold star reinforces and increases the desired behavior by identifying it with something positive. Reinforcement can also be used to extinguish unwanted behaviors by imposing negative consequences.
- Systematic desensitization. Patients imagine a situation they fear, while the therapist employs techniques to help the patient relax, helping the person cope with their fear reaction and eventually eliminate the anxiety altogether. For example, a patient in treatment for agoraphobia, or fear of open or public places, will relax and then picture herself on the sidewalk outside of her house. In her next session, she may relax herself and then imagine a visit to a crowded shopping mall. The imagery of the anxiety-producing situations gets progressively more intense until, eventually, the therapist and patient approach the anxiety-causing situation in real-life (a "graded exposure"), perhaps by visiting a mall. Exposure may be increased to the point of "flooding," providing maximum exposure to the real situation. By repeatedly pairing a desired response (relaxation) with a fear-producing situation (open, public spaces), the patient gradually becomes desensitized to the old response of fear and learns to react with feelings of relaxation.
- Validity testing. Patients are asked to test the validity of the automatic thoughts and schemas they encounter. The therapist may ask the patient to defend or produce evidence that a schema is true. If the patient is unable to meet the challenge, the faulty nature of the schema is exposed.

Initial treatment sessions are typically spent explaining the basic tenets of cognitive-behavioral therapy to the patient and establishing a positive working

WWW.BOOKBAZ.IR

KEY TERMS

Automatic thoughts—Thoughts that automatically come to mind when a particular situation occurs. Cognitive-behavioral therapy seeks to challenge automatic thoughts.

Cognitive restructuring—The process of replacing maladaptive thought patterns with constructive thoughts and beliefs.

Maladaptive—Unsuitable or counterproductive; for example, maladaptive behavior is behavior that is inappropriate to a given situation.

Psychodynamic therapy—A therapeutic approach that assumes dysfunctional or unwanted behavior is caused by unconscious, internal conflicts and focuses on gaining insight into these motivations.

Relaxation technique—A technique used to relieve stress. Exercise, biofeedback, hypnosis, and meditation are all effective relaxation tools. Relaxation techniques are used in cognitive-behavioral therapy to teach patients new ways of coping with stressful situations.

Schemas—Fundamental core beliefs or assumptions that are part of the perceptual filter people use to view the world. Cognitive-behavioral therapy seeks to change maladaptive schemas.

relationship between therapist and patient. Cognitive-behavioral therapy is a collaborative, action-oriented therapy effort. As such, it empowers the patient by giving him an active role in the therapy process and discourages any overdependence on the therapist that may occur in other therapeutic relationships. Therapy is typically administered in an outpatient setting in either an individual or group session. Therapists include psychologists (Ph.D., Psy.D., Ed.D. or M.A. degree), clinical social workers (M.S.W., D.S.W., or L.S.W. degree), counselors (M.A. or M.S. degree), or psychiatrists (M.D. with specialization in psychiatry) and should be trained in cognitive-behavioral techniques, although some brief cognitive-behavioral interventions may be suggested by a primary physician/caregiver. Treatment is relatively short in comparison to some other forms of **psychotherapy**, usually lasting no longer than 16 weeks. Many insurance plans provide reimbursement for cognitive-behavioral therapy services. Because coverage is dependent on the disorder or illness the therapy is treating, patients should check with their individual plans.

Rational-emotive behavior therapy

Rational-emotive behavior therapy (REBT) is a popular variation of cognitive-behavioral therapy developed in 1955 by psychologist Albert Ellis. REBT is based on the belief that a person's past experiences shape their belief system and thinking patterns. People form illogical, irrational thinking patterns that become the cause of both their negative emotions and of further irrational ideas. REBT focuses on helping patients discover these irrational beliefs that guide their behavior and replace them with rational beliefs and thoughts in order to relieve their emotional distress.

There are 10 basic irrational assumptions that trigger maladaptive emotions and behaviors:

- It is a necessity for an adult to be loved and approved of by almost everyone for virtually everything.
- A person must be thoroughly competent, adequate, and successful in all respects.
- Certain people are bad, wicked, or villainous, and should be punished for their sins.
- It is catastrophic when things are not going the way one would like.
- Human unhappiness is externally caused. People have little or no ability to control their sorrows or to rid themselves of negative feelings.
- It is right to be terribly preoccupied with and upset about something that may be dangerous or fearsome.
- It is easier to avoid facing many of life's difficulties and responsibilities than it is to undertake more rewarding forms of self-discipline.
- The past is all-important. Because something once strongly affected someone's life, it should continue to do so indefinitely.
- People and things should be different from the way they are. It is catastrophic if perfect solutions to the grim realities of life are not immediately found.
- Maximal human happiness can be achieved by inertia and inaction or by living passively and without commitment.

Meichenbaum's self-instructional approach

Psychologist Donald Meichenbaum pioneered the self-instructional, or "self-talk," approach to cognitive-behavioral therapy in the 1970s. This approach focuses on changing what people say to themselves, both

internally and out loud. It is based on the belief that an individual's actions follow directly from this self-talk. This type of therapy emphasizes teaching patients coping skills that they can use in a variety of situations to help themselves. The technique used to accomplish this is self-instructional inner dialogue, a method of talking through a problem or situation as it occurs.

Preparation

Patients may seek therapy independently, or be referred for treatment by a primary physician, psychologist, or psychiatrist. Because the patient and therapist work closely together to achieve specific therapeutic objectives, it is important that their working relationship is comfortable and their goals are compatible. Prior to beginning treatment, the patient and therapist should meet for a consultation session, or mutual interview. The consultation gives the therapist the opportunity to make an initial assessment of the patient and recommend a course of treatment and goals for therapy. It also gives the patient an opportunity to find out important details about the therapist's approach to treatment, professional credentials, and any other issues of interest.

In some managed-care clinical settings, an intake interview or evaluation is required before a patient begins therapy. The intake interview is used to evaluate the patient and assign him or her to a therapist. It may be conducted by a psychiatric nurse, counselor, or social worker.

Results

Many patients who undergo cognitive-behavioral therapy successfully learn how to replace their maladaptive thoughts and behaviors with positive ones that facilitate individual growth and happiness. Cognitive-behavioral therapy may be used in conjunction with pharmaceutical and other treatment interventions, so overall success rates are difficult to gauge. However, success rates of 65% or more have been reported with cognitive-behavioral therapy alone as a treatment for panic attacks and agoraphobia. Relapse has been reported in some patient populations, perhaps due to the brief nature of the therapy, but follow-up sessions can put patients back on track.

COLD *see* **Chronic obstructive pulmonary disease**

Cold agglutinins test

Definition

The cold agglutinins test is performed to detect the presence of antibodies in blood that are sensitive to temperature changes. Antibodies are proteins produced by the immune system in response to specific disease agents; autoantibodies are antibodies that the body produces against one of its own substances. Cold agglutinins are autoantibodies that cause red blood cells to clump, but only when the blood is cooled below the normal body temperature of 98.6°F (37°C). The clumping is most pronounced at temperatures below 78°F (25.6°C).

Purpose

The cold agglutinins test is used to confirm the diagnosis of certain diseases that stimulate the body to produce cold agglutinins. The disease most commonly diagnosed by this test is mycoplasmal **pneumonia**, but mononucleosis, **mumps**, **measles**, **scarlet fever**, some parasitic infections, **cirrhosis** of the liver, and some types of **hemolytic anemia** can also cause the formation of cold agglutinins. Hemolytic **anemias** are conditions in which the blood is low in oxygen because the red blood cells are breaking down at a faster rate than their normal life expectancy of 120 days. In addition to these illnesses, some people have a benign condition called chronic cold agglutinin disease, in which exposure to cold causes temporary clumping of red blood cells and consequent numbness in ears, fingers, and toes.

Description

Since cold agglutinins cause red blood cells to clump only at temperatures lower than 98.6°F (37°C), the test consists of chilling a sample of the patient's blood. There is a bedside version of the test in which the doctor collects four or five drops of blood in a small tube, cools the tube in ice water for 30–60 seconds, and looks for clumping of red blood cells. If the cells clump after chilling and unclump as they rewarm, a cold

WWW.BOOKBAZ.IR

KEY TERMS

Agglutinin—An antibody that causes red blood cells to stick or clump together.

Antibody—A protein molecule produced by the immune system that is specific to a disease agent, such as *Mycoplasma pneumoniae*. The antibody combines with the organism and disables it.

Autoantibody—An antibody produced by the body in reaction to any of its own cells or cell products.

Cold agglutinins—Antibodies that cause clumping of red blood cells when the blood temperature falls below normal body temperature (98.6°F/37°C).

Hemolytic anemia—Oxygen deficiency in the blood, caused by shortened survival of red blood cells.

Mycoplasma—A type of free-living microorganism that has no cell wall. Mycoplasmas cause some varieties of pneumonia and urinary tract infections that stimulate the body to produce cold agglutinins.

Titer—The concentration of a substance in a given sample of blood or other tissue fluid.

agglutinin titer (concentration) greater than 1:64 is present. Bedside test results, however, should be confirmed by a laboratory. The laboratory test measures the clumping of red blood cells in different dilutions of the patient's blood serum at 39.2°F (4°C).

Results

The results of the cold agglutinins test require a doctor's interpretation. In general, however, a normal value is lower than 1:32.

Abnormal results

Any value higher than 1:32 suggests a diagnosis of mycoplasmal pneumonia or one of the other viral infections or disease conditions indicated by this test.

Cold sores

Definition

Cold sores are the popular name for mouth sores caused by a type of herpes simplex virus (HSV) known as HSV-1. They are also sometimes referred to as **fever** blisters, herpes labialis, or oral herpes.

Demographics

Cold sores are a commonplace health problem around the world. According to the National Institutes of Health (NIH), about 80% of people in the United States are infected with HSV-1; other estimates give a figure of 90% of all adults worldwide. Most acquire the infection as children from contact with oral fluids from an infected person. Infection with the virus is thought to be equally common in both sexes and all races and ethnic groups. Although infection with HSV-1 is common, only about 10% of infected people actually develop cold sores.

Description

Cold sores are small blisters that form around the outside of the mouth; they should be distinguished from **canker sores**, which form inside the mouth and are not contagious. Caused by a virus known as herpes simplex type 1, cold sores are contagious; direct contact with an infected person may result in contracting the virus. The virus that causes cold sores is related to the herpes simplex virus type 2, HSV-2, that causes **genital herpes**.

Risk factors

People with weakened immune systems, such as patients who have had an organ transplant or are being treated for cancer or HIV infection, are at increased risk of getting cold sores if they are exposed to HSV-1.

Causes and symptoms

Causes

The cause of cold sores is HSV-1. The virus enters the body through tiny breaks in the tissues lining the

A close-up view of a patient's mouth with gingivostomatitis cold sores. *(Custom Medical Stock Photo, Inc.)*

mouth, which is one reason it can easily be spread by kissing or by sharing drinking glasses and other food utensils. The first time a person is infected by the virus, they may simply run a fever without having cold sores. HSV-1 then lies dormant in the cells of the nervous system until it is activated by emotional **stress**, an upper respiratory infection, sun exposure, or some other trigger. It then travels back down the nerves to the skin surface. About 35% of people who get cold sores get them in the same area of skin each time.

Symptoms

Most people who become infected with HSV-1 develop cold sores within 20 days of infection, although symptoms may develop sooner. In most cases, the first eruption of the blisters is preceded by a prodrome, or period of warning symptoms before the main phase of the illness. The prodrome of cold sores usually consists of a tingling, **itching**, or burning sensation that starts one or two days before the blisters appear. The area of skin where the blisters will erupt may swell up, turn red, and be sore to the touch.

The sores themselves last about 7–10 days after they erupt. They appear most commonly on the lips or the area of skin between the upper lip and the nose, but may also appear on the cheeks. Cold sores sometimes appear inside the mouth. Some people may develop a **sore throat**, swelling of the lymph nodes in the neck, or have difficulty swallowing during an outbreak of cold sores.

The blisters associated with cold sores are small and thin-walled, filled with a clear fluid that may ooze out of the sores. HSV-1 is shed in the fluid from the sores and can be transmitted to other people if they come in contact with the blisters. This is the stage in the development of cold sores when the infection is most contagious. After a few days, the blisters break and form a yellow crust that eventually drops off, leaving an area of pinkish skin underneath. There is no permanent scar from a cold sore. Most people who get cold sores have one or two recurrences per year, although some have an outbreak every month.

Diagnosis

Most people can tell whether they have cold sores by the way they feel and where the sores appear. If necessary, the patient's doctor can run a blood test to tell whether the person is infected with HSV-1. This type of test is important if the person is HIV-positive or is being treated with **chemotherapy** for cancer.

Examination

In most cases, people do not need to visit the doctor or dentist for ordinary cold sores. They should make an appointment if they have any of the following symptoms or conditions:

- HIV or any other illness that weakens the immune system
- the cold sores do not heal on their own by the end of two weeks
- the patient's eyes feel sore or irritated
- the cold sores recur frequently
- the blisters are unusually large or painful

Tests

Testing is rarely needed to confirm a diagnosis of cold sores, as the doctor or dentist can usually tell by examining the patient in the office and noting the location of the blisters.

Treatment

Traditional

There is no permanent cure for HSV-1 infection. After a person is infected with the virus, it hides within nerve cells, making it difficult for the immune system to find and destroy it. HSV-1 remains in the body, so that cold sores can reappear at any time. Recurrences of oral herpes can be triggered by a number of factors, including getting the flu or a cold, not getting enough sleep, having dental work or oral surgery, getting traveler's **diarrhea**, menstruation (in women), emotional stress, an injury to the mouth or lips, or exposure to the sun for long periods of time. The connection

WWW.BOOKBAZ.IR

KEY TERMS

Prodrome—A period before the acute phase of a disease when the patient notices characteristic warning symptoms.

Self-limited—A disease that runs its course without the need for professional medical treatment.

Topical—Any medication applied directly to the skin or the surface of the body.

between colds and flu in reactivating HSV-1 is the main reason why oral herpes is commonly known as cold sores or fever blisters.

Drugs

There are some medications that can be used to treat cold sores. The best time to start treating them is during the prodromal stage before the blisters appear. The doctor or dentist can prescribe an antiviral medication to shorten the length of the outbreak and reduce discomfort; the **antiviral drugs** most often prescribed for cold sores are acyclovir (Zovirax), famcyclovir (Famvir), and valacyclovir (Valtrex). Some of these drugs are taken by mouth while others can be applied to the sores as gels or creams. A topical cream containing 10% docosanol, an antiviral drug available without a prescription, has been shown to be an effective treatment for recurrent cold sores. Other treatments that can be used are topical anesthetics applied directly to the sores; and **aspirin**, Advil, or Tylenol to bring down fever.

Therapies for cold sores that are considered experimental include **photodynamic therapy** (PDT) and a medication taken by mouth made from vitamin C combined with a chemical compound derived from pine cones. One group of researchers reported that photodynamic therapy done with lasers reduced the size and swelling of the patients' cold sores but did not reduce the **pain** level or the frequency of recurrences, while a small study of four patients treated with laser PDT reported that all patients experienced at least some pain relief and found that their blisters healed more rapidly. Most observers think that PDT with lasers is a promising form of therapy for recurrent cold sores but needs further research.

Home remedies

Some people find that ice applied to cold sore blisters helps to relieve discomfort, while others are helped by warm compresses. An over-the-counter remedy that works for some people is zinc oxide cream.

Prognosis

Most cases of cold sores heal without any long-term problems, as the disease is considered self-limited; however, HSV-1 can cause an eye infection that may lead to permanent blindness if fluid from the sores gets into the eyes. For this reason it is important for people with cold sores to avoid scratching or squeezing the blisters.

Prevention

The National Institutes of Health (NIH) recommends the following measures to lower the risk of spreading HSV-1 to other parts of the body or to other people, and to lower the frequency of recurrences.

- Avoid kissing or close contact with others while the blisters are present.
- Avoid sharing items that touch the mouth. These include towels, washcloths, lipsticks, lip balms, razors, and toothbrushes as well as drinking glasses and food utensils.
- Keep the hands clean. Wash them frequently and avoid touching the eyes or genital area during an outbreak.
- Avoid putting the fingers in the mouth or biting fingernails.
- Try to avoid such common triggers of cold sores as colds or flu, high stress levels, or being short on sleep.
- Avoid contact sports (football, wrestling, etc.) during an outbreak.
- Use sunblock on the lips and face when outdoors for long periods of time.

Some people with frequent recurrences of cold sores benefit from an over-the-counter dietary supplement called lysine, which is an amino acid (one of the building blocks of proteins). Patients should check with their doctor to see whether lysine might be helpful for them.

People who develop significant related illnesses during cold sore outbreaks, are frequently exposed to sunlight or other known triggers, or have frequent outbreaks of cold sores may wish to ask their doctor or dentist for an antiviral drug to help prevent recurrent outbreaks.

Colic

Definition

Colic is persistent, unexplained crying in a healthy baby between two weeks and five months of age.

Demographics

Colic affects between 10–30% of babies. It occurs equally in male and female babies and is independent of race or ethnicity.

Description

Colic is not a disease. Symptoms of colic usually appear when a baby is 14–21 days old, reach a crescendo at the age of three months, and disappear within the next eight weeks. Episodes occur frequently, but intermittently, and usually begin with prolonged periods of crying in the late afternoon or evening. Crying can last for a few minutes or continue for several hours. Some babies who have colic are simply fussy. Others cry so hard that their faces turn red, then pale.

Causes and symptoms

No one knows what causes colic or why some babies are colicky and others are not. The condition may be the result of swallowing large amounts of air, which becomes trapped in the digestive tract and causes bloating and severe abdominal **pain**.

Other possible causes of colic include:

- digestive tract immaturity
- food intolerances
- hunger or overfeeding
- gastroesophageal reflux
- overheated milk or formula
- overstimulation resulting from noise, light, or activity

WWW.BOOKBAZ.IR

During a colicky episode, babies' bellies often look swollen, feel hard, and make a rumbling sound. Crying intensifies, tapers off, and then gets louder. Many babies grow rigid, clench their fists, curl their toes, and draw their legs toward their body. A burp or a bowel movement can end an attack. Most babies who have colic do not seem to be in pain between attacks.

Diagnosis

Pediatricians and family physicians suspect colic in an infant who:

- has cried loudly for at least three hours a day at least three times a week for three weeks or longer
- is not hungry but cries for several hours between dinnertime and midnight
- demonstrates the clenched fists, rigidity, and other physical traits associated with colic

The baby's medical history and a parent's description of eating, sleeping, and crying patterns are used to confirm a diagnosis of colic. Studies have shown that colic crying is different from regular crying in that it is higher pitched, more turbulent, and more urgent than regular crying. **Physical examination** and laboratory tests are used to rule out infection, intestinal blockage, and other conditions that can cause abdominal pain and other colic-like symptoms.

Treatment

Home remedies

Medications do not cure colic. Doctors sometimes recommend simethicone (Mylicon Drops) to relieve gas pain, but generally advise parents to take a practical approach to the problem.

Gently massaging the baby's back can release a trapped gas bubble, and holding the baby in a sitting position can help prevent air from being swallowed during feedings. Bottle-fed babies can swallow air if nipple holes are either too large or too small.

Nipple-hole size can be checked by filling a bottle with cold formula, turning it upside down, and counting the number of drops released when it is shaken or squeezed. A nipple hole that is the right size will release about one drop of formula every second.

Babies should not be fed every time they cry, but feeding and burping a baby more often may alleviate symptoms of colic. A bottle-fed baby should be burped after every ounce, and a baby who is **breastfeeding** should be burped every five minutes.

KEY TERMS

Gastroesophageal reflux—A condition in which the stomach contents back up into the esophagus. Because the stomach contents are highly acidic, this can cause irritation and heartburn.

When cow's milk is the source of the symptoms, bottle-fed babies should be switched to a soymilk hydrolyzed protein formula. A woman whose baby is breastfeeding should eliminate dairy products from her diet for seven days, then gradually reintroduce them unless the baby's symptoms reappear.

Since intolerance to foods other than cow's milk may also lead to symptoms of colic, breastfeeding women may also relieve their babies' colic by eliminating from their diet:

- coffee
- tea
- cocoa
- citrus
- peanuts
- wheat
- broccoli and other vegetables belonging to the cabbage family

Rocking a baby in a quiet, darkened room can prevent overstimulation, and a baby usually calms down when cuddled in a warm, soft blanket.

Colicky babies cry less when they are soothed by the motion of a wind-up swing, a car ride, or being carried in a parent's arms. Pacifiers can soothe babies who are upset, but a pacifier should never be attached to a string.

Alternatives

Applying gentle pressure to the webbed area between the thumb and index finger of either hand can calm a crying child. So can gently massaging the area directly above the child's navel and the corresponding spot on the spine. Applying warm compresses or holding your hand firmly over the child's abdomen can relieve cramping.

Teas made with chamomile (*Matricaria recutita*), lemon balm (*Melissa officinalis*), peppermint (*Mentha piperita*), or dill (*Anethum graveolens*) can lessen bowel inflammation and reduce gas. A homeopathic combination called "colic" may be effective, and

constitutional homeopathic treatment can help strengthen the child's entire constitution.

A doctor should be notified if a baby who has been diagnosed with colic:

- develops a rectal fever higher than 101°F (38.3°C)
- cries for more than four hours
- vomits
- has diarrhea or stools that are black or bloody
- loses weight
- eats less than normal

Prognosis

Colic is distressing, but it is not dangerous. Symptoms almost always disappear before a child is six months old.

Prevention

Many doctors believe that colic cannot be prevented. Some alternative practitioners, however, feel that colic can be prevented by an awareness of food intolerances and their impact.

Maureen Haggerty
REVISED BY TISH DAVIDSON, A.M.

Colitis

Definition

Colitis, also called ulcerative colitis, is an inflammatory bowel disease closely related to Crohn's disease. In individuals with colitis, the lining of the colon (large intestine) becomes inflamed, cells lining the wall die, and **ulcers** form on the colon wall.

Demographics

In the United States, the prevalence rate of ulcerative colitis is estimated at between 35 and 100 individuals per 100,000 population. This means that more than 2 million Americans have ulcerative colitis, which is a lifelong disease. The disease develops most often before the individual reaches age 30, although it can develop as late as age 60. People of Jewish ethnicity appear to be more likely to develop ulcerative colitis, and women are slightly more likely to develop colitis than men. The disease is less common in South America, Asia, and Africa than in the United States.

Description

Colitis is an inflammatory bowel disease of uncertain origin. In this disease, the lining of the colon and rectum become inflamed and develop sores (ulcers) that produce pus and mucus. In mild cases, only the lining of the intestine is affected, but in severe cases, these ulcers may penetrate deeper layers of the colon or even perforate (break through) the colon wall. In ulcerative colitis, the inflamed area is continuous and develops only in the rectum and colon. This condition contrasts with Crohn's disease (a related inflammatory bowel disease), in which the inflamed area develops in patches and can occur in

A specimen of a colon indicating ulcerative colitis. *(Photo Researchers, Inc.)*

WWW.BOOKBAZ.IR

multiple places in the digestive system from the mouth to the rectum. There is no cure for ulcerative colitis, although treatment can bring symptoms under control or cause them to go into remission (disappear) for long periods.

Causes and symptoms

The cause of colitis is unclear. As of 2014, scientists believed that people who develop colitis carry an inherited susceptibility to developing the disease. Research has shown that people who have a parent or sibling with colitis are more likely to also develop colitis, and if one identical twins is affected, it is highly likely the other will also have the disease. However, inheritance does not completely predict who will develop colitis. Researchers believe that when a person with an inherited susceptibility to the disease is exposed to an outside agent, an inappropriate autoimmune reaction is triggered. As a result, the immune system attacks the body's own cells lining the intestine. No single outside trigger agent has been isolated. Suspect agents include bacteria, viruses, and environmental toxins. In the past, it was thought that **food allergies** could trigger colitis. Practitioners of conventional medicine subsequently determined that this was not the cause, although some alternative medical practitioners continued to accept the food allergy theory.

Symptoms associated with colitis include abdominal **pain** and cramps; frequent, urgent bowel movements; **diarrhea** with blood, pus, and mucus in the stool; and **fever**. Other signs of colitis occur because the disease interferes with the ability of the digestive system to absorb nutrients. These symptoms include **fatigue**, loss of appetite, weight loss, **dehydration**, and in severe cases, electrolyte imbalance. Because the immune system responds inappropriately, other parts of the body may be affected. The individual may develop joint pain, liver, kidney, and eye problems, and skin **rashes**. Although colitis is not caused by **stress** or food **allergies**, stress and certain foods (e.g., milk) tend to worsen symptoms.

Diagnosis

Symptoms of colitis mimic those of several other bowel diseases. Colitis is often diagnosed after extensive testing has ruled out other causes. After a **health history** and **physical examination**, the physician will order additional tests, including blood tests and a stool sample. The stool sample is examined for blood and parasites. Imaging tests include a **barium enema** and x rays of the intestine. By cleansing the intestine and filling it with barium, a white, chalky, non-toxic substance, abnormalities of the bowel are more easily seen on the x-ray film. **Ultrasound** and computed tomography, two non-invasive imaging techniques, may also be done. A definitive diagnosis usually is obtained by a **colonoscopy**, an invasive procedure that allows the physician to examine the colon lining for the entire length of the colon.

KEY TERMS

Colonoscopy—A procedure in which the colon is cleansed and the a lighted fiber optic instrument is inserted through the anus to allow the physician to view the entire length of the colon and detect abnormalities in the colon lining, including polyps and ulcers.

Electrolyte—Ions in the body that participate in metabolic reactions. The major human electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), phosphate (HPO_4^{2-}), bicarbonate (HCO^{3-}), and sulfate (SO_4^{2-}).

Rectum—The last few inches of the large intestine that store waste until it is eliminated from the body through the anus.

Steroid—A family of compounds that share a similar chemical structure. This family includes estrogen and testosterone, vitamin D, cholesterol, and the drugs cortisone and prednisone.

Treatment

The goal of colitis treatment is to control symptoms and improve quality of life. As of 2014, there was no cure for the disease. Conventional medicine treats the symptoms of ulcerative colitis primarily with drugs, although conventional practitioners also may recommend some complementary therapies suggested in the following text. Treatment is individualized and depends on the severity of the disease and the specific symptoms of the individual.

Drugs

Drug treatment depends on the severity of symptoms and whether ulcerative colitis is active or in remission. Anti-inflammatory drugs are at the heart of drug treatment for ulcerative colitis. Sulfasalazine (Azulfidine, EN-Tabs) is the most common anti-inflammatory drug used to treat mild to moderate ulcerative colitis because patients can safely take it for long maintenance periods, and it can be given

with other drugs. Other anti-inflammatory drugs include mesalamine (Pentasa, Asacol, Rowasa, Canasa) and Balsalazide (Colazal). If these drugs do not provide adequate symptom relief, patients may be given **corticosteroids** such as prednisone and methylprednisolone. Corticosteroid drugs have substantial side effects and can be taken only for a short time during symptom flare-ups.

Medications used to treat diarrhea symptoms include diphenoxylate (Lomotil, Lofene), and loperamide (Imodium, Kaopectate). Anticholinergic drugs, which block the communication between nerves and muscles and thus reduce contraction of the intestine, include hyoscyamine (Anaspaz Cystospaz), and dicyclomine (Bentyl).

People with severe symptoms and complications beyond the digestive system may be hospitalized and given intravenous (IV) steroid drugs or drugs that suppress the immune system. These include the **tumor necrosis factor** inhibitor drug infliximab (Remicade), azathioprine (Imuran), cyclosporine (Neoral, Sandimmune), and 6-mercaptopurine (Purinethol). Since colitis is suspected of being caused by an inappropriate immune system response, suppressing the activity of the immune system may reduce symptoms. Once a flare-up is controlled, the individual continues on a maintenance dose of some combination of diarrhea-control, anti-inflammatory, and **immunosuppressant drugs**.

Surgery

Between 25% and 40% of people with ulcerative colitis develop symptoms so severe that they eventually need surgery (a colectomy) to remove their colon. When the colon is removed, the final portion of the small intestine is connected to a hole (stoma) in the abdomen. The individual wears a bag outside the body to collect waste. The bag must be emptied at regular intervals. Alternately, if part of the rectum is left intact the small intestine may be connected directly to the rectum after the colon is removed. Waste leaves the body through the anus in the regular manner. Bowel movements are more frequent and watery, as fluid that would normally be absorbed in the colon now passes out of the body.

Diet

Certain foods seem to worsen symptoms of colitis in many people. Individuals must determine their own problem foods and learn to avoid them. General suggestions for dietary changes that help many people include the following:

- Drink 8–10 glasses of water or clear fluids daily to prevent dehydration, which is especially important for people who have frequent watery bowel movements.
- Avoid high fiber foods. If symptoms are under control, some high-fiber foods may gradually be added back into the diet.
- Experiment with whether dairy products worsen symptoms; many people find that milk and cheese seem to exacerbate their symptoms.
- Avoid caffeine because it stimulates the digestive tract.
- Avoid drinking alcohol.
- Eat a low-fat diet.
- Eat smaller, more frequent meals.

Alternatives

HERBS. Certain herbal remedies have been shown to improve symptoms for some people. These include the following:

- Psyllium. Recommended by both alternative and conventional physicians, psyllium absorbs water and adds bulk to the stool.
- Boswellia resin (*Boswellia sacra*) is thought to have anti-inflammatory properties. In a small study, when taken with sulfasalazine (a pharmaceutical drug), it increased the number of patients whose symptoms went into remission.
- Aloe (*Aloe vera*) juice or oral gel is thought to improve the chance of remission.
- Turmeric (*Curcuma longa*) is thought to have useful anti-inflammatory properties.

SUPPLEMENTS. Many people with moderate to severe symptoms develop vitamin and mineral deficiencies that need to be corrected with supplements and/or a multivitamin. Alternative practitioners also recommend a wide range of supplements that have shown mixed results in small trials. Some of these are:

- Probiotics. Probiotics are beneficial living organisms, usually bacteria that supplement the beneficial bacteria normally found in the intestines. Some studies have found that a non-disease producing strain of *Escherichia coli* helps some people with ulcerative colitis remain in remission. Probiotics and their effects on digestive diseases were active areas of research in 2014. Several Food and Drug Administration approved clinical trials of probiotics are being conducted in the United States for people with colitis. Information on trials enrolling participants is available at http://www.clinicaltrials.gov.

WWW.BOOKBAZ.IR

- Fish oil. Some studies have found that fish oil supplements increased weight gain and decreased the need for anti-inflammatory drugs, while others found fish oil was ineffective in patients with ulcerative colitis.
- Folic acid (Vitamin B_9). Sulfasalazine inhibits the absorption of folic acid, so people taking this drug may need supplementation. However, taking folic acid supplements can mask a vitamin B_{12} deficiency, so people taking folic acid may also need to take B_{12}. A physician should be consulted before taking these vitamins.
- Dehydroepiandrosterone (DHEA). This natural steroid hormone is produced in small amounts by the body. In studies, improvement was seen only with large supplement doses with a high likelihood of undesirable side effects.
- Iron. People who have a lot of blood in their stool are at risk of becoming iron deficient (anemic).

HOME REMEDIES. Although stress does not cause colitis, it often worsens symptoms, so **stress reduction** techniques such as the following should be incorporated into the daily routine.

- Mild to moderate exercise can help stabilize bowel function and improve mood.
- Yoga helps to relax the body and relieve tension.
- Meditation calms the body and mind.
- Biofeedback training helps individuals have more control over their body and allows individuals to consciously enter a relaxed state.
- Support groups allow people to share tips and frustrations in an atmosphere of mutual understanding.

Prognosis

Colitis cannot be cured. Most people go though periods of remission followed by periods of flare-ups when symptoms worsen. Remission can last from months to years depending on the individual.

Prevention

Ulcerative colitis cannot be prevented. About 5% of people who have ulcerative colitis later develop **colon cancer**. Regular yearly colonoscopies can detect colon cancer early when it can be easily treated.

Colon cancer

Definition

Cancer of the colon is a disease characterized by the development of malignant cells in the lining or epithelium of the large intestine. Malignant cells have lost normal control mechanisms governing growth. These cells may invade surrounding local tissue or they may spread throughout the body and invade other organ systems.

Synonyms for the colon include the large bowel or the large intestine. The rectum is the continuation of the large intestine into the pelvis that terminates in the anus.

Demographics

There are at least 100,000 new cases of colon cancer diagnosed per year in the United States. Excluding skin cancers, colorectal cancer is the fourth most commonly diagnosed cancer in both men and women in the United States. Colorectal cancer is the second leading cause of deaths from cancer. The death rate from colon cancer has been declining for the last 30 years. The decline in the

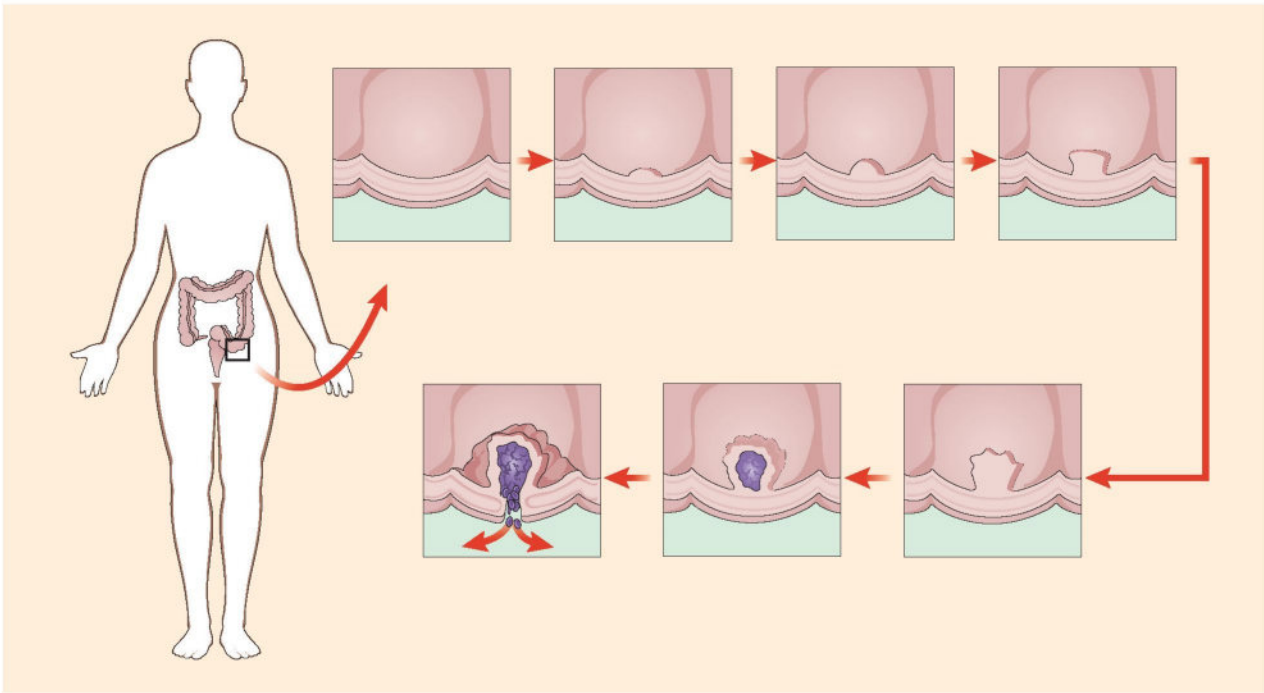

Illustration showing the development of a cancerous tumor within the colon. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

death rate is attributed to more accurate screening procedures, which find and make possible the removal of problematic polyps before they convert to cancer. Screening also facilitates finding cancer in earlier, more treatable stages. In addition, treatment methodologies for colon cancer have improved dramatically over the last decade.

There are over one million colon cancer survivors in the United States alone.

Approximately one-third of colon cancer cases are associated with familial clustering. First degree relatives of patients with newly diagnosed colorectal adenomas or invasive colorectal cancer are considered to be at high risk for the development of the disease and should be screened for the presence of colorectal cancer.

Description

Risk factors

Several risk factors are related to the development of colon cancer including:

- increasing age; most cases of colon cancer are diagnosed after age 50
- personal history of colon polyps or colorectal cancer
- personal history of inflammatory bowel disease such as ulcerative colitis or Crohn's disease
- family history of colorectal cancer, especially in a first degree relative (parent of sibling)
- presence of an inherited syndrome such as familial adenomatous polyposis (FAP) and hereditary non–polyposis colorectal cancer (HNPCC). Between 5% and 10% of people have an inherited gene that causes colorectal cancer. The two most common types of these syndromes are FAP and HNPCC.
- African American race
- Jews of Eastern European descent (Ashkenazi Jews). Members of this ethnic group have some of the highest rates of colorectal cancer in the world.
- consuming a diet high in red meats, processed meats, and cooking foods at high temperatures
- physical inactivity
- obesity
- history of smoking
- history of heavy alcohol use
- personal history of type II diabetes

The colon is a tubular organ beginning in the right lower abdomen. It ascends on the right side of the abdomen, traverses from right to left in the upper abdomen, descends vertically down the left side,

WWW.BOOKBAZ.IR

takes an S–shaped curve in the lower left abdomen, and then flows into the rectum as it leaves the abdomen for the pelvis. These portions of the colon are named separately although they are part of the same organ.

- cecum, the beginning of the colon
- ascending colon, the right vertical ascent of the colon
- transverse colon, the portion traversing from right to left
- descending colon, the left vertical descent of the colon
- sigmoid colon, the S–shaped segment of colon above the pelvis

These portions of the colon are recognized anatomically based on the arterial blood supply and venous and lymphatic drainage of these segments of the colon. Lymph, a protein–rich fluid that bathes the cells of the body, is transported in small channels known as lymphatics that run alongside the veins of the colon. Lymph nodes are small filters through which the lymph travels on its way back to the bloodstream. Cancer can spread elsewhere in the body by invading the lymph and vascular systems. Therefore, these anatomic considerations become very important in the treatment of colon cancer.

The small intestine is the continuation of the upper gastrointestinal tract responsible for carrying ingested nutrients into the body. The waste left after the small intestine has completed absorption of nutrients amounts to about a quart (a few liters), of material per day and is directly delivered to the colon, (at the cecum), for processing. The colon is responsible for the preservation of fluid and electrolytes as it propels the increasingly solid waste toward the rectum and anus for excretion.

When cells lining the colon become malignant, they first grow locally and may invade partially or totally through the wall of the bowel and even into adjacent structures and organs. In the process, the tumor can penetrate and invade the lymphatics or the capillaries locally and gain access to the circulation. As the malignant cells work their way to other areas of the body, they again become locally invasive in the new area to which they have spread. These tumor deposits, originating from the colon primary tumor, are then known as metastases. If metastases are found in the regional lymph nodes from the primary, they are known as regional metastases, or regional nodal metastases. If they are distant from the primary tumor, they are known as distant metastases. The patient with distant metastases has systemic disease. Thus the cancer originating in the colon begins locally and, given time, can become systemic.

In most cases, colon cancer develops slowly over several years. Prior to a cancer's developing, a non–cancerous polyp may appear on the inner lining of the colon. A polyp typically begins as a benign (non–cancerous) growth of tissue. Over time, some polyps can convert into cancerous tumors.

There are two major types of polyps, adenomatous polyps (adenomas) and hyperplastic and inflammatory polyps. Adenomatous polyps are considered pre–cancerous lesions while hyperplastic and inflammatory polyps are generally not pre–cancerous.

Some individuals may have evidence of dysplasia (cells look abnormal) in the lining of the colon. These abnormal–looking cells may transform to cancerous cells over time. Individuals with a history of Crohn's disease or ulcerative **colitis** may show evidence of dysplasia in the colon.

More than 95% of colorectal cancers are classified as adenocarcinomas. This type of cancer originates from glands that secrete mucus which lubricates the lining of the colon.

Causes and symptoms

Causes

Carcinogenesis is the process by which agents in the environment may induce mutation. It is caused by agents known as **carcinogens** (cancer–causing agents). Specific carcinogens related to the development of colon cancer have been difficult to identify; however, dietary factors seem to be involved.

Colon cancer is more common in industrialized nations. **Diets** high in fat, red meat, total calories, and alcohol seem to predispose people to the disease. Diets high in fiber appear to decrease risk. High–fiber diets may help lessen exposure of the colon lining to carcinogens from the environment, as the transit time through the bowel is faster with a high–fiber diet than it is with a low fiber diet.

Age plays a definite role in the predisposition to colon cancer. Two-thirds of all cases occur after age 50 and the average age for those who develop the disease is 62.

There is also a increased risk for colon cancer in the individual who smokes.

Patients who have inflammatory diseases of the colon known as ulcerative colitis and Crohn's colitis are also at increased risk.

KEY TERMS

Adenocarcinoma—Type of cancer beginning in glandular epithelium.

Adjuvant therapy—Treatment involving radiation, chemotherapy (drug treatment), or hormone therapy, or a combination of all three given after the primary treatment for the possibility of residual microscopic disease.

Anastomosis—Surgical reconnection of the ends of the bowel after removal of a portion of the bowel.

Anemia—The condition caused by too few circulating red blood cells, often manifested in part by fatigue.

Carcinogens—Substances in the environment that cause cancer, presumably by inducing mutations, with prolonged exposure.

Electolytes—Salts, such as sodium and chloride.

Epithelium—Cells composing the lining of an organ.

Lymph nodes—Cellular filters through which lymphatics flow.

Lymphatics—Channels that are conduits for lymph.

Malignant—Cells that have been altered such that they have lost normal control mechanisms and are capable of local invasion and spread to other areas of the body.

Metastasis—Site of invasive tumor growth that originated from a malignancy elsewhere in the body.

Mutation—A change in the genetic makeup of a cell that may occur spontaneously or be environmentally induced.

Occult blood—Presence of blood that cannot be seen with the naked eye.

Polyps—Localized growths of the epithelium that can be benign, precancerous, or harbor malignancy.

Radical resection—Surgical resection that takes the blood supply and lymph system supplying the organ along with the organ.

Resect—To remove surgically.

Sacrum—Posterior bony wall of the pelvis.

Systemic—Throughout the body.

Researchers know there is a genetic link to many cases of colon cancer, those called familial cases. This type of colon cancer tends to run in families. In late 2003, a team of researchers identified the specific location on a human chromosome by analyzing blood samples from 53 families in which at least one member had a colon cancer or precancerous colon polyp.

The development of polyps of the colon almost always precedes the development of colon cancer by five or more years. Polyps are benign growths of the colon lining. They can be unrelated to cancer, precancerous, or malignant. Polyps, when identified, are removed for diagnosis. If the polyps are benign, the patient should undergo careful surveillance for the development of more polyps or the development of colon cancer.

Symptoms

Colon cancer causes symptoms related to its local presence in the large bowel or by its effect on other organs if it has spread. These symptoms may occur alone or in combination:

- a change in bowel habit
- blood in the stool
- bloating, persistent abdominal distention
- constipation
- a feeling of fullness even after having a bowel movement
- narrowing of the stool—so–called ribbon stools
- persistent, chronic fatigue
- abdominal discomfort
- unexplained weight loss
- (very rarely) nausea and vomiting

Most of these symptoms are caused by the physical presence of the tumor mass in the colon. Similar symptoms can be caused by other processes; they are not absolutely specific to colon cancer. The key is recognizing that the persistence of these symptoms without ready explanation should prompt the individual to seek medical evaluation.

If a tumor develops in the colon, it will begin to cause symptoms as it reaches a certain size. The symptoms are caused by the tumor blocking the opening in the colon. In addition, the tumor commonly oozes blood that is lost in the stool. (Often, this blood is not visible.) This condition results in anemia and chronic **fatigue**. Weight loss is a late symptom, often implying substantial obstruction or the presence of systemic disease.

Diagnosis

In all other cancers (breast and prostate, for example), screening tests look for small, malignant lesions. Screening for colorectal cancers, however, involves the search for pre–malignant, benign polyps. This

WWW.BOOKBAZ.IR

screening can be close to 100% effective in preventing cancer development, not just in detecting small cancers.

Screening involves physical exam, simple laboratory tests, and the visualization of the lining of the colon. To visualize the colon epithelium, clinicians use x rays (indirect visualization) and **endoscopy** (direct visualization).

Examination

The **physical examination** involves the performance of a digital rectal exam (DRE). The DRE includes manual examination of the rectum, anus and the prostate. During this examination, the physician examines the anus and the surrounding skin for **hemorrhoids**, abscesses, and other irregularities. After lubricating the gloved finger and anus, the examiner gently slides the finger into the anus and follows the contours of the rectum. The examiner notes the tone of the anus and feels the walls and the edges for texture, tenderness, and masses as far as the examining finger can reach. At the time of this exam, the physician checks the stool on the examining glove with a chemical to see if any occult (invisible), blood is present. At home, after having a bowel movement, the patient is asked to swipe a sample of stool obtained with a small stick on a card. After three such specimens are on the card, the card is then easily chemically tested for occult blood also. (The stool analysis mentioned here is known as a **fecal occult blood test**, or FOBT, and, while it can be helpful, it is not 100% accurate. Only about 50% of cancers are FOBT–positive.) These exams are accomplished as an easy part of a routine yearly physical exam.

Tests

Proteins are sometimes produced by cancers and these may be elevated in the patient's blood. When this occurs, the protein produced is known as a tumor marker. There is a tumor marker for some cancers of the colon; it is known as carcinoembryonic antigen, or CEA. Unfortunately, this protein may be made by other adenocarcinomas as well, or it may not be produced by a particular colon cancer. Therefore, screening by chemical analysis for CEA has not been helpful. CEA has been helpful when used in a follow–up role for patients treated for colon cancer if their tumor makes the protein.

Procedures

Indirect visualization of the colon may be accomplished by inserting a compound of barium into the rectum and filling the colon with this compound. Barium compounds produce a white contrast image of the lining of the colon on x ray and thus the contour of the lining of the colon may be seen. Detail can be increased if the barium utilized is thinned and air also introduced. These studies are known as the **barium enema** (BE), and the double contrast barium enema (DCBE).

Direct visualization of the colon lining is accomplished using a scope or endoscope. The physician introduces the instrument through the rectum. Older, shorter scopes were rigid. Today, utilizing fiberoptic technology, the scopes are flexible and can reach into the colon much farther. If the left colon only is visualized, it is called flexible **sigmoidoscopy**. When the entire colon is visualized, the procedure is known as **colonoscopy**.

A procedure called virtual colonoscopy has been developed but debate continues on whether or not it is effective as colonoscopy. Virtual colonoscopy refers to the use of imaging, usually with computed tomography (CT) scans or **magnetic resonance imaging** (MRI) to produce images of the colon. Studies have shown that virtual colonoscopy is as effective as colonoscopy for screening purposes and it offers the advantage of being less invasive and less risky. However, many physicians are unwilling to accept it as a replacement for colonoscopy, particularly since some patients might still require the regular colonoscopy as a follow–up to the virtual procedure if a polyp or abnormality is found that requires biopsy.

Unlike the indirect visualizations of the colon (the BE and the DCBE), endoscopic screenings allow a physician to remove polyps and to biopsy suspicious tissue. (A biopsy is a removal of tissue for examination by a pathologist.) For this reason, many physicians prefer endoscopic screening. All of the visualizations, the BE, DCBE, and each type of endoscopy, require pre–procedure preparation (evacuation) of the colon.

If patients have symptoms that could possibly be related to colon cancer, the entire colon will be examined. The combination of a flexible sigmoidoscopy and DCBE may be performed, but the preferred evaluation of the entire colon and rectum is a complete colonoscopy. Colonoscopy allows direct visualization, photography, and the opportunity to obtain a biopsy of any abnormality visualized. If, for technical reasons, the entire colon is not visualized endoscopically, a DCBE should complement the colonoscopy.

The diagnosis of colon cancer is actually made by the performance of a biopsy of any abnormal lesion in the colon. When a tumor growth is identified, it could be either a benign polyp (or lesion) or a cancer; the

biopsy resolves the issue. The endoscopist may take many samples to exclude any sampling errors.

If the patient has advanced disease at the time of diagnosis, areas where the tumor has spread (such as the liver) may be amenable to biopsy. Such biopsies are usually obtained using a special needle under local **anesthesia**.

Once a diagnosis of colon cancer has been established by biopsy, in addition to the physical exam, studies will be performed to assess the extent of the disease. Blood studies include a **complete blood count**, **liver function tests**, and a CEA. Imaging studies will include a CT scan (computed tomography scan) of the chest, abdomen, and pelvis. The scans will determine if the cancer has spread to the lung, will evaluate potential spread to the liver, and can determine whether any local spread of the primary tumor has occurred. If the patient has any neurologic symptoms, a CT scan of the brain will be performed, and if the patient is experiencing bone **pain**, a **bone scan** also will be performed.

Treatments

Once the diagnosis has been confirmed by biopsy, the clinical stage of the cancer is assigned. Stage is determined based on the characteristics of the primary tumor, its depth of penetration through the bowel, and the presence or absence of regional or distant metastases. Often, the depth of penetration through the bowel or the presence of regional lymph nodes can not be assigned before surgery.

Colon cancer is assigned stages I through IV, based on the following general criteria:

- Stage I: The tumor is confined to the epithelium or has not penetrated through the first layer of muscle in the bowel wall.
- Stage II: The tumor has penetrated through to the outer wall of the colon or has gone through it, possibly invading other local tissue.
- Stage III: The tumor has developed to include regional lymph node involvement.
- Stage IV: The cancer has spread to at least one distant organ (such as the liver or lungs) or lymph nodes, or has spread to a distant part of the peritoneum.

With many cancers other than colon cancer, staging plays an important role to best determine treatment options. Colon cancers are also graded based on how closely the cancer cells resemble normal cells. The grading scale is G1 to G4 with cells graded as G1 looking the most normal and cells graded as G4 looking the most abnormal. Low grade tumors (G1) tend to grow more slowly and are less likely to metastasize to distant organs which may result in a better prognosis.

Traditional

SURGERY. Almost all colon cancers are treated with surgery first, regardless of stage. Colon cancers through Stage III, and even some Stage IV colon cancers, are treated with surgery first, before any other treatments are considered.

Surgical removal of the involved segment of colon (colectomy) along with its blood supply and regional lymph nodes is the primary therapy for colon cancer. Usually, the partial colectomies are separated into right, left, transverse, or sigmoid sections based on the blood supply. The removal of the blood supply at its origin along with the regional lymph nodes that accompany it ensures an adequate margin of normal colon on either side of the primary tumor. When the cancer lies in a position such that the blood supply and lymph drainage between two of the major vessels, both vessels are taken to assure complete radical resection or removal (extended radical right or left colectomy). If the primary tumor penetrates through the bowel wall, any tissue adjacent to the tumor extension is also taken, if feasible.

Surgery is used as primary therapy for stages I through III colon cancer unless there are signs that local invasion will not permit complete removal of the tumor, as may occur in advanced stage III tumors. However, this circumstance is rare, occurring in less than 2% of all colon cancer cases.

After the resection is completed, the ends of the remaining colon are reconstructed; the reattachment is called an anastomosis. Once healing has occurred, there may be a slight increase in the frequency of bowel movements. This effect usually lasts only for several weeks. Most patients go on to develop completely normal bowel function.

Occasionally, the anastomosis is risky and cannot be performed. When the anastomosis cannot be performed, a **colostomy** is performed instead. A colostomy is performed by bringing the end of the colon through the abdominal wall and sewing it to the skin. The patient will have to wear an appliance (a bag) to manage the stool. The colostomy may be temporary and the patient may undergo a reattachment at a later, safer date, or the colostomy may be permanent. In most cases, emergent colostomies are not reversed and are permanent.

RADIATION. Radiation therapy is used as an adjunct to surgery if there is concern about potential

WWW.BOOKBAZ.IR

for local recurrence post–operatively and the area of concern will tolerate the radiation. For instance, if the tumor invaded muscle of the abdominal wall but was not completely removed, this area would be considered for radiation. Radiation may also be given in combination with **chemotherapy** prior to surgery (neoadjuvant therapy) to shrink the size of the tumor. Radiation has significant dose limits when residual bowel is exposed to it because the small and large intestine do not tolerate radiation well.

CHEMOTHERAPY. Chemotherapy is useful for patients who have had all identifiable tumor removed and are at risk for recurrence (adjuvant chemotherapy). The FOLFOX chemotherapy regimen is a common regimen administered as adjuvant therapy in the treatment of colon cancer. This regimen includes the drugs oxaliplatin, 5–FU, and leucovorin. The drugs 5–FU and leucovorin given in combination or the drug capcetibine given alone may also be used. Adjuvant chemotherapy administered after surgery may be continued for a total of six months of chemotherapy.

TARGETED THERAPIES. Targeted therapies work in ways that are different from the way chemotherapy works. Targeted therapies, as the name implies, target specific proteins on the cellular structures of cancer cells in an attempt to kill the cancer cells. The advantage of targeted therapy is that normal cells which do not contain the abnormal proteins the cancer cells contain are usually not affected by the targeted therapy. Therefore, side effects of these drugs are often less pronounced than the side effects from chemotherapy. Targeted therapy drugs used to treat colon cancer include bevacizumab (Avastin), cetuximab (Erbitux), and panitumumab (Vectibix).

Prognosis

Prognosis is the long–term outlook or survival after therapy. As expected, the survival rates are dependent upon the stage of the cancer at the time of diagnosis, making early detection crucial.

Colon cancer is highly treatable and often curable if detected when the cancer is localized in the bowel. Surgery is the primary treatment choice for most cases of colon cancer and results in a cure for about 50% of patients.

Five year survival rates for colon cancer range from 74% in patients diagnosed with Stage I disease to 6% for patients diagnosed in Stage IV.

Prevention

There is not an absolute method for preventing colon cancer. Still, there are steps an individual can take to dramatically lessen the risk or to identify the precursors of colon cancer so that it does not manifest itself. The patient with a familial history can enter screening and surveillance programs earlier than the general population. High–fiber diets and **vitamins**, avoiding **obesity**, and staying active lessen the risk. Avoiding cigarettes and alcohol may be helpful. By controlling these environmental factors, an individual can lessen risk and to this degree prevent the disease.

People who turn age 50, and all of those with a history of colon cancer in their families (even if younger than age 50), should speak with their physicians about the most recent screening recommendations from physician and cancer organizations. They should watch for symptoms and attend all recommended screenings to increase the likelihood of catching colon cancer early.

Colon therapy *see* **Colonic irrigation**

Colonic irrigation

Definition

Colonic irrigation is also known as **hydrotherapy** of the colon, high colonic, entero-lavage, or simply colonic. It is the process of cleansing the colon by passing several gallons of water through it with the use of special equipment. It is similar to an enema but treats the whole colon, not just the lower bowel. This has the effect of flushing out impacted fecal matter, toxins, mucous, and even parasites, that often build up over the passage of time. It is a procedure that should only be undertaken by a qualified practitioner.

Demographics

Colon and bowel cancer are two of the leading causes of death in the United States, and alternative practitioners insist that it can be prevented by efficient hygiene procedures. Providing that care is taken to replace the natural organisms that flourish in the bowel, many health benefits can be expected from colonic irrigation. In general, alternative practitioners maintain that an ill-functioning bowel is the source of all disease, and, therefore, keeping it clean will be an effective protection against this.

The cost of colonic irrigation treatments varies, but is generally $35–70 per session, which may last from 45 minutes to one hour. The cost of the machine itself is $4,000–12,000, but again, it should be noted that only qualified therapists should conduct sessions.

Purpose

Anyone suffering from gas, bloating, cramping pains, **acne** and other skin complaints, arthritis, and a list of bowel complaints such as **diverticulitis** and irritable bowel etc., may benefit from colonic irrigation. In particular, cancer patients are often advised to undertake a course of colonic irrigation sessions as an essential part of their treatment. When a biological cancer therapy begins to enable the body to breakdown a cancerous mass, it is essential that speedy and effective elimination of the resulting toxins is achieved.

Removing large amounts of toxic matter relieves the patient and can lead to the alleviation of symptoms such as arthritis, **chronic fatigue syndrome**, **candidiasis**, and a host of other illnesses. Properly executed, colonic irrigation can help restore normal peristaltic action to a sluggish bowel, thus reducing the need for more hydrotherapy treatments over time. In addition, removing the layer of fecal matter which coats the intestines in many individuals allows improved assimilation of the nutrients from foods and can alleviate symptoms of vitamin and other nutrient deficiencies. Many alternative health practitioners consider some form of hydrotherapy for the bowel to be essential in the treatment of degenerative diseases.

Description

Origins

Cleansing the colon with the use of hydrotherapy is not a new concept. Forms of colonic irrigation have been used successfully for decades to relieve chronic toxicity and even acute cases of toxemia.

Over time, many people develop a thick layer of fecal matter that coats their colon. It hardens and becomes impacted, reducing the efficiency of the bowel, and in some cases, completely obstructing normal elimination of waste matter from the body. It is quite common for people to have only one bowel movement per day, and some as few as one or two per week.

Alternative practitioners advise that we probably should have one bowel movement for every meal that we eat. If not, then we are not eliminating wastes completely, and if input exceeds output, then we will surely suffer the consequences at some point.

Incomplete elimination of body wastes may result in the following, depending on where the deposits end up:

- sluggish system
- joint pain and arthritis
- irritable bowel syndrome
- diverticulitis
- Crohn's disease

WWW.BOOKBAZ.IR

- leaky gut syndrome
- heart problem
- migraine
- allergies
- bad breath
- acne and other skin problems such as psoriasis
- asthma
- early senility and Alzheimer's disease
- chronic fatigue syndrome
- cancer, particularly of the bowel
- multiple sclerosis

During colonic irrigation, a small speculum is passed into the patient's bowel through the rectum. This is attached to a tube, which leads to a machine that pumps temperature-controlled water into the colon at a controlled rate (to be controlled by either the practitioner or the patient). The temperature of the water should ideally be kept as close to body temperature as possible.

The patient will temporarily be filled with water up to the level of the entire colon. Patients say they can feel the water up under their ribs but that the process, although sometimes uncomfortable, is not painful. The amount of water will vary but will generally be in the region of between two and six liters (or quarts) at any one time. This triggers peristaltic action and the patient will begin to expel the water along with fecal matter back through the tube and into the machine.

The fecal matter is flushed out through a viewing tube, so that what is eliminated may be monitored. Quite often, unsuspected parasites are expelled, along with very old fecal material, very dark in color, which may have been in the colon for years. Some therapists comment that it looks like **aging** rubber.

During the treatment, the therapist will gently massage the patient's abdomen to help dislodge impacted fecal matter. In addition to massage, sometimes **acupressure**, **reflexology**, or lymphatic drainage techniques may be used to loosen deposits and stimulate the bowel. It is important that the right amount of water is used, as too much will cause discomfort and too little will be ineffective. If correctly done, colonic irrigation is not painful at all and some patients claim to sleep through their treatment.

Sanitation is vital to this process. The tubes and speculums used are generally disposable, but other parts of the machine, such as the viewing tube, must be sterilized after each patient.

Normally, a series of treatments will be required to achieve desired results regarding the elimination of impacted, decaying matter, and restoration of bowel regularity. Initially only gas and recent fecal matter may be expelled. The residue attached to the colon wall is usually the result of years of neglect, and therapists say that one cannot expect complete relief in only one session.

Impacted fecal matter can cause an imbalance of the natural organisms that normally populate the bowel, causing what is known as dysbiosis. Under ideal conditions, the bowel is populated by a variety of naturally occurring organisms. It seems that the enzymes occurring in fresh fruit and vegetables encourage these beneficial organisms. One of the results of eating processed denatured foods is that this natural balance is upset, and food may begin to rot in the bowel instead of being processed.

Decomposing matter can cause a toxic condition and may lead to many health problems, as **constipation** causes backed up pollution of the body cells. The process of repair and elimination of wastes enters a downward spiral which at best will cause **fatigue**, lack of energy and premature aging, and, at worst, can cause degenerative diseases, among them **allergies**, and even cancer and Alzheimer's disease.

Preparations

Most practitioners prefer that distilled or purified water is used for colonic irrigation, but others use sterilized tap water.

Precautions

It may be advisable to use a probiotic pessary after colonic irrigation, to ensure replacement of desirable natural flora. There are certain conditions that either partly or completely preclude the use of colonic irrigation, such as an active attack of Crohn's disease, bleeding **ulcers**, and hyperacidosis. If in doubt, a qualified practitioner should be consulted. Anyone suffering from these conditions should always notify the practitioner when receiving colonic irrigation treatments.

Side effects

Some allopathic practitioners claim that colonic irrigation flushes out essential electrolytes and friendly bacteria from the bowel and that it can be dangerous. Practitioners counter that this can easily be remedied with the use of **probiotics**, and that in any case, these possible disadvantages are easily offset by the benefits

KEY TERMS

Dysbiosis—The condition that results when the natural flora of the gut are thrown out of balance, such as when antibiotics are taken.

Peristalsis—The natural wave-like action of a healthy bowel that transports matter from one end of the bowel to the other.

Probiotics—Supplements of beneficial microorganisms that normally colonize the gut.

Toxemia—Poisoning of the blood.

of having large amounts of putrefying matter, harmful organisms, and parasites removed from the system.

Research and general acceptance

Although many alternative health care practitioners swear by colonic irrigation, there is a large allopathic lobby that claims that there are no benefits to be had, and that there are dangers involved. However, there are many decades of records and research from the alternative health care community that indicate that this therapy may have a valuable place in the treatment of degenerative diseases and toxic conditions.

Colonoscopy

Definition

Colonoscopy is an endoscopic medical procedure that uses a colonoscope, a long, flexible, thin, lighted tube-like instrument containing a tiny video camera, which allows a visual examination of the lining of the colon (large intestine) and rectum.

Description

Colonoscopy can be performed either in a physician's office or in an endoscopic procedure room of a hospital or freestanding clinic. For otherwise healthy patients, colonoscopy is usually performed by a gastroenterologist or surgeon in an office or clinic setting. When performed on patients with other medical conditions that could cause complications or that require hospitalization, the procedure is usually performed in the **endoscopy** department of a hospital where more intensive physiologic monitoring and/or general **anesthesia** can be better provided.

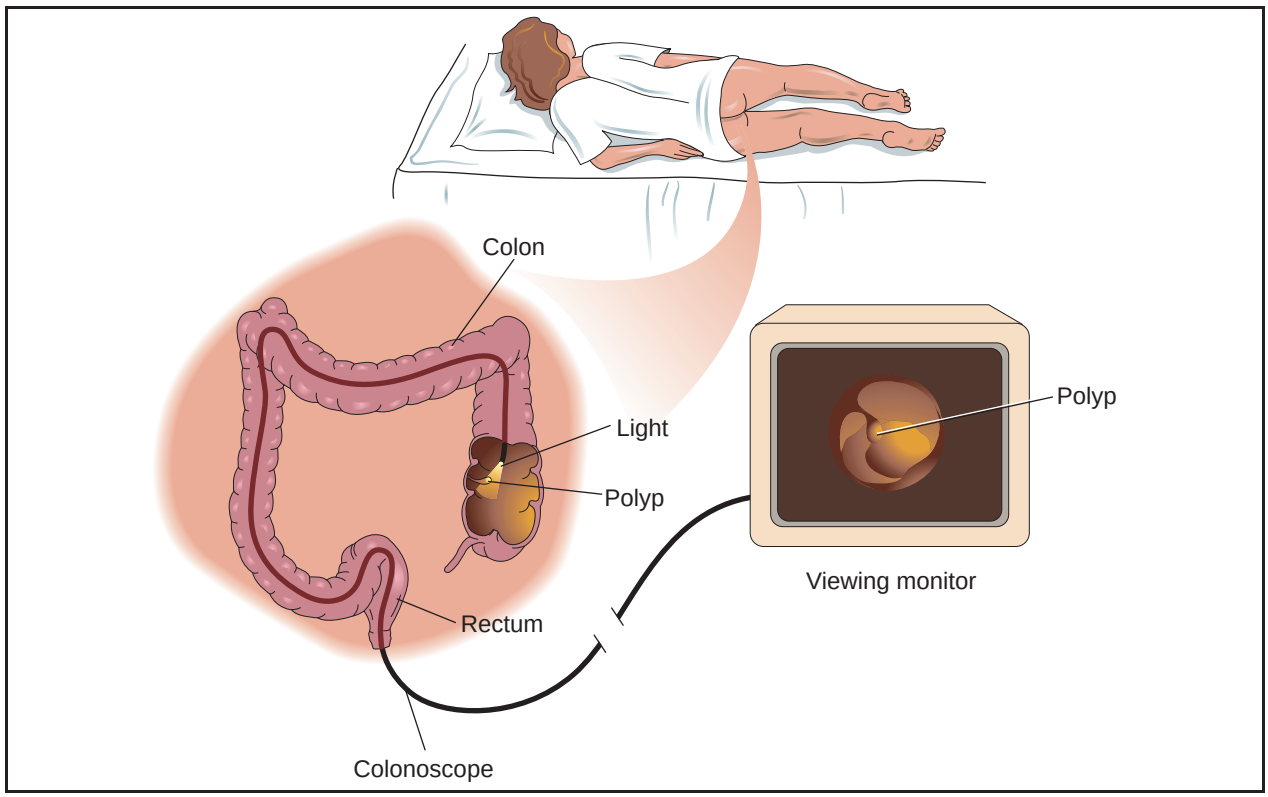
Purpose

A colonoscopy is generally recommended when the individual complains of rectal bleeding, has a change in bowel habits, and/or has other unexplained abdominal symptoms. The test is frequently used to look for colorectal cancer, especially when polyps or tumor-like growths have been detected by a **barium enema** examination and other diagnostic imaging tests. Polyps can be removed through the colonoscope, and samples of tissue (biopsies) can be taken to detect the presence of cancerous cells. In addition, colonoscopy can be used to remove foreign bodies from the colon, control hemorrhaging, and excise tumors.

A colonoscopy allows the physician to view the lining of the entire colon; therefore, it also enables physicians to check for bowel diseases such as ulcerative **colitis** and Crohn's disease. The United States Centers for Disease Control and Protection Prevention Task Force recommends everyone have a screening colonoscopy starting at age 50 and at least every 10 years thereafter to screen for polyps and colorectal cancer. Individuals with a family history of colorectal cancer and those with a history of polyps should begin screening earlier and be screened more frequently.

An intravenous line is usually inserted into a vein in the patient's arm to administer a sedative and a painkiller. During the colonoscopy, patients lie on their side with their knees drawn up toward the abdomen. The doctor begins the procedure by inserting a lubricated, gloved finger into the anus to check for any abnormal masses or blockage. A thin, well-lubricated colonoscope is then inserted into the anus and gently advanced through the colon. The lining of the large intestine is examined through the colonoscope. The physician views images on a television monitor, and the procedure can be documented using a video recorder. Still images can be recorded and saved on a computer disk or printed. Occasionally, air may be pumped through the colonoscope to help clear the path or open the colon. If excessive secretion, stool,

WWW.BOOKBAZ.IR



Colonoscopy is a procedure where a long and flexible tubular instrument called a colonoscope is inserted into the patient's anus in order to view the lining of the colon and rectum. It is performed to test for colorectal cancer and other bowel diseases, and enables the physician to collect tissue samples for laboratory analysis. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

or blood obstructs the viewing, it is suctioned out through the scope. The doctor may press on the abdomen or ask the patient to change position in order to advance the scope through the colon.

The entire length of the large intestine can be examined in this manner. If suspicious growths are present, tiny biopsy forceps or brushes are inserted through the colon and tissue samples (biopsies) are obtained. Small polyps or inflamed tissue also can be removed using tiny instruments passed through the scope. For removing tumors or performing other types of surgery on the colon during colonoscopy, an electrosurgical device or laser system may be used in conjunction with the colonoscope. To stop bleeding in the colon, a laser, heater probe, or electrical probe is used, or special medicines are injected through the scope. After the procedure, the colonoscope is slowly withdrawn and the instilled air is allowed to escape. The anal area is then cleansed with tissues. Biopsy samples are sent to a clinical laboratory, where they are analyzed by a pathologist.

The procedure takes from 30 minutes to two hours depending on how easy it is to advance the scope through the colon. Colonoscopy can be a long and uncomfortable procedure, and the bowel-cleansing preparation may be tiring and can produce **diarrhea** and cramping. During the colonoscopy, the sedative and the **pain** medications keep the patient drowsy and relaxed. Some patients complain of minor discomfort and pressure from the colonoscope; however, the sedative and pain medication usually cause most patients to dose off during the procedure.

Virtual colonoscopy

Virtual colonoscopy is a newer, less invasive technique for screening for colon polyps and cancer. The colon is cleaned out using potent **laxatives** just as it is for a standard colonoscopy. Instead of obtaining pictures through the insertion of a colonoscope, virtual colonoscopy uses x-ray images from a computerized tomography (CT) scan or **magnetic resonance imaging** (MRI) to create through computer manipulation two- and three-dimensional pictures of the colon.

A thin tube is inserted into the anus and air is introduced to expand the colon. The individual is

KEY TERMS

Barium enema—An x-ray test of the bowel performed after giving the patient an enema of a white chalky substance (barium) that outlines the colon and the rectum.

Biopsy—A procedure in which a sample of suspicious tissue is removed and examined for cancer or other disease by a pathologist.

Colonoscope—A thin, flexible, hollow, lighted tube that is inserted through the anus and rectum into the colon to enable the physician to view the entire lining of the colon.

Computed tomography (CT) scan—A radiologic imaging technique that uses computer processing to generate an image of the tissue density; also called computerized axial tomography (CAT) and computerized transaxial tomography (CTAT).

Crohn's disease—A chronic inflammatory disease that generally starts in the gastrointestinal tract and causes the immune system to attack one's own body.

Diverticulosis—A condition that involves the development of sacs that bulge through the large intestine's muscular walls but are not inflamed. It may cause bleeding, stomach distress, and excess gas.

Electrosurgical device—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures; often used in conjunction with laparoscopy.

Magnetic resonance imaging (MRI)—A test that provides pictures of organs and structures inside the body using radio waves. In many cases, an MRI provides information that cannot be obtained from x-ray tests.

Pathologist—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

Polyps—An abnormal growth that develops on the inside of a hollow organ such as the colon.

Sigmoidoscopy—A process of passing a long, hollow tubular instrument through the anus in order to permit inspection, diagnosis, treatment, and imaging, especially of the sigmoid flexure.

Ulcerative colitis—A chronic condition in which recurrent ulcers are found in the colon. Its symptoms are abdominal cramping and rectal bleeding.

then slid into a tube where x rays are used to produce images. The individual will be asked to change positions during the procedure. After the procedure is finished, the images will be combined and manipulated to show any abnormalities.

Virtual colonoscopy offers several advantages. The procedure is less invasive than an endoscopic colonoscopy. It does not require patients to be sedated or put under anesthesia and is a good option for individuals who cannot or will not undergo standard colonoscopy. The procedure can be performed in less than one minute, compared with about 30–60 minutes plus recovery time required for standard colonoscopy. Another benefit of the CT scan is that it can find polyps that occasionally are missed by colonoscopy because the polyps lie behind folds within the colon.

Disadvantages of virtual colonoscopy include the following:

- It has difficulty finding small polyps (<0.2 in [5 mm] in size) that are easily seen in a colonoscopy.
- It is less able to find flat polyps compared to a colonoscopy.
- Small pieces of stool can look like polyps on the CT scan and lead to a diagnosis of polyp when there is none.
- It is not possible to remove suspect polyps or take a biopsy. If polyps are found by virtual colonoscopy, a standard colonoscopy must be done to remove the polyps. In such cases, individuals must undergo two procedures.

Preparation

Preparation is substantially the same for endoscopic and virtual colonoscopy. Patients who regularly take **aspirin**, **nonsteroidal anti-inflammatory drugs** (NSAIDs), blood thinners, or insulin should be sure to inform the physician at the time the colonoscopy is scheduled. The physician also should be notified if patients have **allergies** to any medications or anesthetics, bleeding problems, or are pregnant. The doctor should be informed of all medications patients are taking and if they have had a barium enema x-ray examination recently. If patients have had heart valves replaced, the doctor should be informed so that appropriate **antibiotics** can be administered to prevent infection. Patients with severe active colitis, extremely dilated colon (toxic megacolon), or severely inflamed bowel may not be candidates for colonoscopy. Patients requiring continuous ambulatory peritoneal dialysis are generally not candidates for endoscopic

WWW.BOOKBAZ.IR

colonoscopy due to a higher risk of developing internal bleeding. The risks associated with the procedure are explained to the patients beforehand, and patients are asked to sign a consent form.

The colon must be thoroughly cleansed before performing colonoscopy. Consequently, for about two days before the procedure, considerable preparation is necessary to clear the colon of all stool. Patients are asked to refrain from eating any solid food for 24–48 hours before the test. Only clear liquid such as juices, broth, and gelatin are allowed. Red or purple juices should be avoided, since they can cause coloring of the colon that may be misinterpreted as blood during the colonoscopy. Patients are advised to drink plenty of water to avoid **dehydration**. A day before the colonoscopy, patients are prescribed liquid, tablet, and/or suppository laxatives by the physician. In addition, commercial **enemas** may be prescribed. Patients are given specific instructions on how and when to use the laxatives and/or enemas. This preparatory emptying of the colon assures that the colonoscope will not be obstructed and that the physician will be able to clearly see the colon lining.

On the morning of the colonoscopy, patients are not to eat or drink anything. Unless otherwise instructed by the physician, they should continue to take all current medications. **Vitamins** with iron, iron supplements, or iron preparations should be discontinued for a few weeks before the colonoscopy because iron residue in the colon can inhibit viewing during the procedure. These preparatory procedures are extremely important to ensure a thoroughly clean colon for examination.

Aftercare

After the procedure, endoscopic colonoscopy patients are kept under observation until the medication wears off. Patients must be driven home and can generally resume a normal diet and usual activities unless otherwise instructed. Patients are advised to drink plenty of fluids to replace those lost by laxatives and **fasting**.

For a few hours after the procedure, endoscopic patients may feel groggy; this is not a concern for patients who have a virtual colonoscopy where no anesthesia has been administered. There may be some abdominal cramping and a considerable amount of gas may be passed. If a biopsy was performed or a polyp was removed, there may be small amounts of blood in the stool for a few days. If patients experiences severe abdominal pain or have persistent and heavy bleeding, this information should be brought to the physician's attention immediately.

Results

The results are normal if the lining of the colon is a pale reddish pink and there are no abnormal masses visible. In this case, patients probably will not have to undergo another colonoscopy for several years.

Abnormal results indicate polyps or other suspicious masses in the lining of the colon. Many polyps can be removed during the endoscopic procedure, and tissue samples can be taken by biopsy. Abnormalities observed during a virtual colonoscopy must be clarified by an endoscopic colonoscopy and biopsies. If cancerous cells are detected in the tissue samples, then a diagnosis of **colon cancer** is made. A pathologist analyzes the tumor cells further to estimate the tumor's aggressiveness and the extent of the disease. This is crucial before deciding on the mode of treatment for the disease. Abnormal findings could also be due to inflammatory bowel diseases such as ulcerative colitis or Crohn's disease. **Diverticulosis**, which causes many small finger-like pouches to protrude from the colon wall, may also contribute to an abnormal result in the colonoscopy.

Risks

Both endoscopic and virtual colonoscopies are practically free of complications and risks. Rarely, (two in 1,000 cases) a perforation (hole) may occur in the intestinal wall. Also in endoscopic colonoscopies heavy bleeding due to the removal of the polyp or from the biopsy site occurs infrequently in endoscopic colonoscopies (one in 1,000 cases). Also, some endoscopic patients may have adverse reactions to the sedatives administered during the colonoscopy, but severe reactions are very rare. Infections due to a colonoscopy are also extremely rare. Patients with artificial or abnormal heart valves are usually given antibiotics before and after the procedure to prevent an infection.

Colorectal cancer is the third leading cause of cancer deaths in both men and women in the United States. In 2014, the American Cancer Society estimated that about 96,800 new cases of colon cancer and 40,000 new cases of **rectal cancer** would be diagnosed. Combined, these cancers would cause about 50,300 deaths that year. The World Health Organization (WHO) estimates that about 500,000 people worldwide die from colorectal cancer each year.

Regular screening after age 50 is the best way to prevent colorectal cancer. Small polyps may indicate

a precancerous condition and should be removed. The Affordable Care Act (Obamacare) requires this routine screening to be covered by insurance plans.

Individuals with a strong family history of colorectal cancer may wish to undergo genetic screening to detect a genetic alteration that may identify people who are more likely to develop the disease and who would benefit from earlier and more frequent screening. Only about 5% of colorectal cancers are inherited, so **genetic testing** provides limited benefits for most of the population.

Color blindness

Definition

Color blindness, also called color vision deficiency (CVD), is a group of conditions that affect the perception of color, characterized by the inability to clearly distinguish different colors of the spectrum. The difficulties range from mild to severe. Color blindness is a misleading term because people with color blindness are not blind. Rather, they tend to see colors in a limited range of hues; a rare few may not see colors at all.

Demographics

In the United States, red–green color vision defects are the most common form of color vision deficiency. This condition affects males more often than females. Some 10 million American men (7% of the male population) either cannot distinguish red from green, or see red and green differently from most people. This is the most common form of color blindness, and it affects only 0.4% of women. Blue–yellow color vision defects affect males and females equally. This condition occurs in fewer than 1 in 10,000 people worldwide. Complete achromatopsia affects an estimated 1 in 30,000 people. The condition much more prevalent among Pingelapese islanders, who live on one of the Eastern Caroline Islands of Micronesia. Some 5–10% of this population have a total absence of color vision.

Description

Normal color vision requires the use of specialized receptor cells called cones, which are located in the retina of the eye. There are three types of cones, termed red, blue, and green. Each cone contains a special pigment, called a photopigment, that is most sensitive to a particular wavelength of light. The combined input from all three types of cones produces normal color vision. An abnormality, or deficiency, of any of the types of cones will result in abnormal color vision.

There are three basic variants of color blindness. Red–green color blindness is by far the most common deficiency. Affected persons cannot distinguish well between shades of red and green. They see these colors differently than most people and may experience difficulty naming different hues.

Blue–yellow color blindness is an inability to distinguish both blue and yellow, which are seen as white or gray. The condition is quite rare. Red–green and

WWW.BOOKBAZ.IR

blue–yellow color vision deficiency disrupt the perception of color, but do not affect the sharpness of vision.

A total inability to distinguish colors (achromatopsia) is exceedingly rare. These affected individuals view the world in shades of gray. They frequently have poor visual acuity and are extremely sensitive to light (photophobia), which causes them to squint in ordinary light.

Risk factors

A family history of color blindness increases the risk since most color vision problems are inherited. Another risk factor for color vision deficiency is **aging**. The eye's lens can darken and yellow over time, which can impair the ability of older adults to see dark colors. Certain medications can also increase risk. For example, the drug hydroxychloroquine (Plaquenil), used to treat **rheumatoid arthritis**, can cause color blindness.

Causes and symptoms

Mutations in the CNGA3, CNGB3, GNAT2, OPN1LW, OPN1MW, and OPN1SW genes are known to cause color vision deficiency. The OPN1LW gene makes pigments (L cones) that are more sensitive to light at the red end of the visible spectrum while the OPN1MW gene makes pigments (M cones) that are more sensitive to yellow–green light in the middle of the visible spectrum. As for the OPN1SW gene, it makes pigments (S cones) that are more sensitive to blue–violet light at the end of the visible spectrum. Genetic changes involving the OPN1LW and OPN1MW genes accordingly lead to an absence of L or M cones or the production of abnormal cones that affect red–green color vision. Mutations of the OPN1SW gene leads to the premature destruction of S cones or the production of defective cones which impairs perception of the color blue and makes it difficult to detect differences between shades of blue and green. As for the CNGA3, CNGB3, and GNAT2 genes, their mutation is responsible for achromatopsia.

Color blindness is sometimes acquired. Chronic illnesses that can lead to color blindness include Alzheimer disease, **diabetes mellitus**, **glaucoma**, leukemia, **liver disease**, chronic **alcoholism**, **macular degeneration**, **multiple sclerosis**, Parkinson disease, sickle cell anemia, and **retinitis pigmentosa**. Accidents or strokes that damage the retina or affect particular areas of the brain can lead to color blindness. Some medications such as **antibiotics**, **barbiturates**, anti–tuberculosis drugs, high blood pressure medications, and several medications used to treat nervous disorders and psychological problems may cause color blindness. Industrial or environmental chemicals such as carbon monoxide, carbon disulfide, fertilizers, styrene, and some containing lead can cause loss of color vision. Occasionally, changes can occur in the affected person's capacity to see colors after age 60.

KEY TERMS

Achromatopsia—The inability to distinguish any colors.

Cones—Receptor cells that allow the perception of colors.

Photophobia—An extreme sensitivity to light.

Photopigment—Pigment that is most sensitive to a particular wavelength of light.

Retina—The light–sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Rod—Photoreceptor that is highly sensitive to low levels of light and transmits images in shades of gray.

The inability to correctly identify colors is the only sign of color blindness. It is important to note that people with red/green or blue varieties of color blindness use other cues such as color saturation and object shape or location to distinguish colors. They can often distinguish red or green if they can visually compare the colors. However, most have difficulty accurately identifying colors without any other references. Most people with any impairment in color vision learn colors, as do other young children. These individuals often reach adolescence before their visual deficiency is identified.

Diagnosis

Tests

There are several tests available to identify problems associated with color vision. The most commonly used is the American Optical/Hardy, Rand, and Ritter Pseudoisochromatic test. It is composed of several discs filled with colored dots of different sizes and colors. A person with normal color vision looking at a test item sees a number that is clearly located somewhere in the center of a circle of variously colored dots. A color–blind person is not able to distinguish the number.

The Ishihara test is comprised of eight plates that are similar to the American Optical Pseudoisochromatic test plates. The individual being tested looks for numbers among the various colored dots on each test plate. Some plates distinguish between red/green and blue color blindness. Individuals with normal color vision perceive one number. Those with red/green color deficiency see a different number. Those with blue color vision see yet a different number.

A third analytical tool is the Titmus II Vision Tester Color Perception test. The subject looks into a stereoscopic machine. The test stimulus most often used in professional offices contains six different designs or numbers on a black background, framed in a yellow border. Titmus II can test one eye at a time. However, its value is limited because it can only identify red/green deficiencies and is not highly accurate.

Treatment

There is no treatment or cure for color blindness. Most color vision deficient persons compensate well for their abnormality and usually rely on color cues and details that are not consciously evident to persons with typical color vision.

Clinical trials

Clinical trials on color blindness and related conditions are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2009, NIH reported 15 on–going or recently completed studies on vision deficiency.

A few examples include:

- A study measuring color vision in patients with a blue light filtering lens implant in one eye and non–tinted implant in the other eye to determine whether blue light filtering lenses limit color vision. (NCT00403143)
- Evaluation of optical coherence tomography (OCT) scanners, instruments that use a beam of light to measure the thickness of the retina, the light–sensitive inner lining of the back of the eye. (NCT00069199)
- A genetic study of patients with retinal dystrophies, conditions responsible for numerous cases of blindness. (NCT00422721)

Clinical trial information is constantly updated by NIH and the most recent information on blindness trials can be found at: http://clinicaltrials.gov.

Prognosis

In the case of some types of acquired color deficiency, if the cause of the problem is removed, the condition may improve with time. But for most people with acquired color blindness, the damage is usually permanent.

Prevention

Color blindness cannot be prevented.

Colostomy

Definition

A colostomy is a surgical procedure that brings a portion of the large intestine through the abdominal wall to carry feces out of the body.

Purpose

A colostomy is a means to treat various disorders of the large intestine, including cancer, bowel obstruction, inflammatory bowel disease, ruptured diverticulum, ischemia (compromised blood supply), or traumatic injury. Temporary colostomies are created to divert stool from injured or diseased portions of the large intestine, allowing rest and healing. Permanent colostomies are performed when the distal bowel (at the farthest distance) must be removed or is blocked and inoperable. Although colorectal cancer is the most common indication for a permanent colostomy, only about 10–15% of patients with this diagnosis require a colostomy.

Demographics

Estimates of all **ostomy** surgeries (those involving any opening from the abdomen for the removal of either feces or urine) range from 70,000 to 120,000 in the United States each year, with a little over one-third being colostomies. In the United Kingdom, approximately 21,000 stoma operations are performed each year, of which 6,500 are permanent colostomies, according to the UK Colostomy Association. According to the Cleveland Clinic, less than 10% of patients with **rectal cancer** and 1% of patients with **colon cancer** need permanent colostomies.

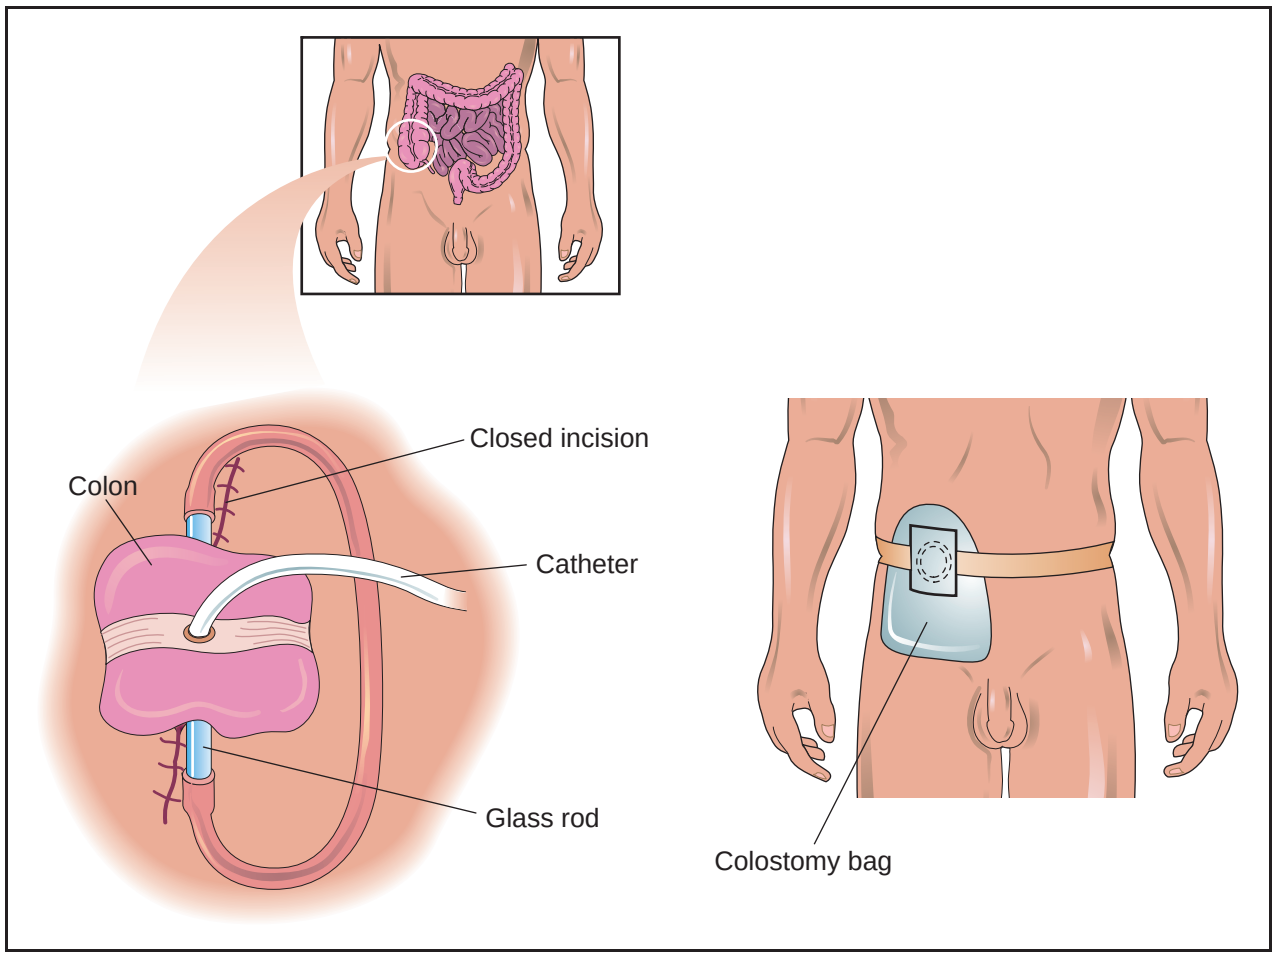
Description

Surgery will result in one of three types of colostomies:

- In an end colostomy, the functioning end of the intestine (the section of bowel that remains connected to the upper gastrointestinal tract) is brought out onto the surface of the abdomen, forming the stoma (artificial opening) by cuffing the intestine back on itself and suturing the end to the skin. The surface of the stoma is actually the lining of the intestine, usually appearing moist and pink. The distal portion of bowel (now connected only to the rectum) may be removed, or sutured closed and left in the abdomen. An end colostomy is usually a permanent ostomy, resulting from trauma, cancer, or another pathological condition.
- Double-barrel colostomy involves the creation of two separate stomas on the abdominal wall. The proximal (nearest) stoma is the functional end that is connected to the upper gastrointestinal tract and will drain the stool; the distal stoma, connected to the rectum and also called a mucous fistula, drains small amounts of mucus material. This is most often a temporary colostomy performed to rest an area of bowel and is later closed.
- A loop colostomy is so-called because the surgeon brings a loop of bowel through an incision in the abdominal wall. The loop is held in place outside the abdomen by a plastic rod slipped beneath it. An incision is made in the bowel to allow the passage of stool through the loop colostomy. The supporting rod is removed approximately seven to ten days after surgery, when healing has occurred that will prevent the loop of bowel from retracting into the abdomen. A loop colostomy is most often performed for creation of a temporary stoma to divert stool away from an area of intestine that has been blocked or ruptured.

Diagnosis

A number of diseases and injuries may require a colostomy. Among the diseases are inflammatory



A colostomy is a surgical procedure in which a portion of the large intestine, or colon, is brought through the abdominal wall to carry feces out of the body. There are three types of colostomies: end colostomy, double-barrel colostomy, and loop colostomy. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

bowel disease and colorectal cancer. Determining whether this surgery is necessary is a decision the physician makes based on a number of factors, including patient history, amount of **pain**, and the results of tests such as a **colonoscopy** and lower GI (gastrointestinal) series. Due to the surgery's impact on a person's lifestyle, the decision is made after careful consultation with the patient. However, an immediate decision may be made in emergency situations involving injuries or puncture **wounds** in the abdomen or intestinal perforations related to diverticular disease, **ulcers**, or life-threatening cancer.

Preparation

As with any surgical procedure, the patient will be required to sign a consent form after the procedure is explained thoroughly. Blood and urine studies, along with various x rays and an electrocardiograph (EKG), may be ordered as the doctor deems necessary. If possible, the patient should visit an enterostomal therapist, who will mark an appropriate place on the abdomen for the stoma and offer preoperative education on ostomy management.

In order to empty and cleanse the bowel, the patient may be placed on a low-residue diet for several days prior to surgery. A liquid diet may be ordered for at least the day before surgery, with nothing by mouth after midnight. A series of **enemas** and/or oral preparations (GoLytely or Colyte) may be ordered to empty the bowel of stool. Oral or intravenous **antibiotics** may be ordered to decrease bacteria in the intestine and help prevent postoperative infection. A **nasogastric tube** is inserted from the nose to the stomach on the day of surgery or during surgery to remove gastric secretions and prevent **nausea and vomiting**. A urinary catheter (a thin plastic tube) may also be inserted

WWW.BOOKBAZ.IR

to keep the bladder empty during surgery, giving more space in the surgical field and decreasing chances of accidental injury.

Aftercare

Postoperative care for the patient with a new colostomy, as with any patient who has undergone major surgery, involves monitoring of blood pressure, pulse, respiration, and temperature. Breathing tends to be shallow because of the effects of **anesthesia** and pain caused by the abdominal incision. The patient is instructed how to support the operative site during deep breathing and coughing and may be given pain medication if necessary. Fluid intake and output is measured, and the operative site is observed for color and amount of wound drainage. The nasogastric tube will remain in place, attached to low, intermittent suction until bowel activity resumes. For the first 24–48 hours after surgery, the colostomy will drain bloody mucus. Fluids and electrolytes are infused intravenously until the patient's diet can gradually be resumed, beginning with liquids. Usually within 72 hours, passage of gas and stool through the stoma begins. Initially, the stool is liquid, gradually thickening as the patient begins to take solid foods. The patient is usually out of bed in 8–24 hours after surgery and discharged in two to four days.

A colostomy pouch will generally have been placed on the patient's abdomen around the stoma during surgery. During the hospital stay, the patient and his or her caregivers will be educated on how to care for the colostomy. Determination of appropriate pouching supplies and a schedule of how often to change the pouch should be established. Regular assessment and meticulous care of the skin surrounding the stoma is important to maintain an adequate surface on which to attach the pouch. Some patients with colostomies are able to routinely irrigate the stoma, resulting in regulation of bowel function; rather than needing to wear a pouch, these patients may only need a dressing or cap over their stoma. Often, an enterostomal therapist will visit the patient in the hospital or at home after discharge to help the patient with stoma care.

Dietary counseling will be necessary for the patient to maintain normal bowel function and to avoid **constipation**, impaction, and other discomforts.

Risks

Potential complications of colostomy surgery include:

- excessive bleeding
- surgical wound infection
- thrombophlebitis (inflammation and blood clot to veins in the legs)
- pneumonia
- pulmonary embolism (blood clot or air bubble in the lungs' blood supply)

Psychological complications may result from colostomy surgery because of the fear of the perceived social stigma attached to wearing a colostomy bag. Patients may also be depressed and have feelings of low self-worth because of the change in their lifestyle and their appearance. Some patients may feel physically and sexually unattractive and may worry that their spouse or significant other will no longer find them appealing. Counseling and education regarding surgery and the inherent lifestyle changes are often necessary.

Obesity

Patients who are severely overweight or obese face a higher risk of complications from colostomy surgery and from abdominal surgery in general. **Obesity** is a risk factor for stoma failure, as it is more difficult for the surgeon to identify the optimal site for the stoma and more difficult for the patient to provide proper care for the stoma. There are higher rates of wound infection and cardiopulmonary complications in obese patients than in the general population, either due to obesity itself or any concurrent obesity-related conditions, such as high blood pressure (**hypertension**), type 2 diabetes, and **heart disease**.

Mortality rates for colostomy patients vary according to the patient's general health upon admittance to the hospital. Even among higher risk patients, mortality is about 16%. This rate is greatly reduced (between 0.8% and 3.8%) when the colostomy is performed by a board-certified colon and rectal surgeon.

Results

Complete healing is expected without complications. The period of time required for recovery from the surgery may vary depending on the patient's overall health prior to surgery and the patient's willingness to participate in stoma care. The colostomy patient without other medical complications should be able to resume all daily activities once recovered from the surgery. Adjustments in diet and daily personal care will need to be made.

Complications after colostomy surgery can occur. The doctor should be made aware of any of the following problems after surgery:

- increased pain, swelling, redness, drainage, or bleeding in the surgical area
- headache, muscle aches, dizziness, or fever
- increased abdominal pain or swelling, constipation, nausea or vomiting, or black, tarry stools

Stomal complications can also occur. They include:

- Death (necrosis) of stomal tissue. Caused by inadequate blood supply, this complication is usually visible 12–24 hours after the operation and may require additional surgery.
- Retraction (stoma is flush with the abdomen surface or has moved below it). Caused by insufficient stomal length, this complication may be managed by use of special pouching supplies. Elective revision of the stoma is also an option.
- Prolapse (stoma increases length above the surface of the abdomen). Most often this results from an overly large opening in the abdominal wall or inadequate fixation of the bowel to the abdominal wall. Surgical correction is required when blood supply is compromised.
- Stenosis (narrowing at the opening of the stoma). Often this is associated with infection around the stoma or scarring. Mild stenosis can be removed under local anesthesia; severe stenosis may require surgery for reshaping the stoma.
- Parastomal hernia (bowel causing bulge in the abdominal wall next to the stoma). This occurs due to placement of the stoma where the abdominal wall is weak or an overly large opening in the abdominal wall was made. The use of an ostomy support belt and special pouching supplies may be adequate. If severe, the defect in the abdominal wall should be repaired and the stoma moved to another location.

Alternatives

When a colostomy is deemed necessary, there are usually no alternatives to the surgery, though there can be alternatives in the type of surgery involved and adjuvant therapies related to the disease. For example, laparoscopic surgery is being used with many diseases of the intestinal tract, including initial cancers. For this surgery, the colon and rectal surgeon inserts a laparoscope (an instrument that has a tiny video camera attached) through a small incision in the abdomen. Other small incisions are made for the surgeon to insert laparoscopic instruments to use in creating the colostomy. Laparoscopic surgery often results in shorter hospital stays, reduced postoperative pain, quicker recovery, and far less scarring. It is not recommended for patients who have had extensive prior abdominal surgery, large tumors, previous cancer, or serious heart problems.

KEY TERMS

Diverticulum—Pouches that project off the wall of the intestine.

Embolism—Blockage of a blood vessel by any small piece of material traveling in the blood; the emboli may be caused by germs, air, blood clots, or fat.

Enema—Insertion of a tube into the rectum to infuse fluid into the bowel and encourage a bowel movement. Ordinary enemas contain tap water, mixtures of soap and water, glycerine and water, or other materials.

Intestine—Commonly called the bowels, divided into the small and large intestine. They extend from the stomach to the anus.

Ischemia—A compromise in blood supply delivered to body tissues that causes tissue damage or death.

Ostomy—A surgical procedure that creates an opening from the inside of the body to the outside, usually to remove body wastes (feces or urine).

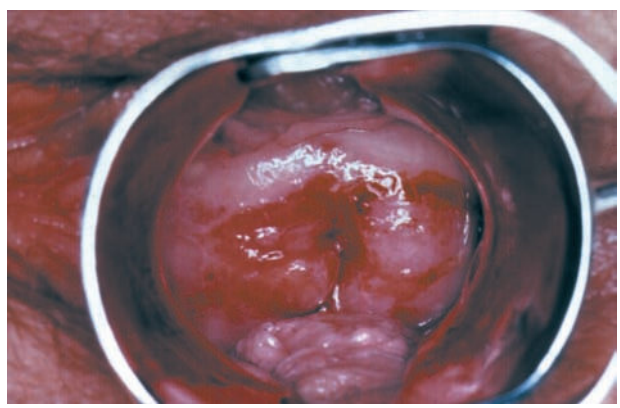
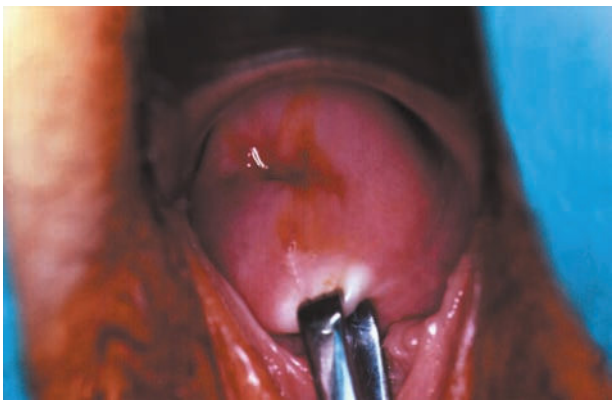
Colposcopy

Definition

Colposcopy is a procedure that allows a physician to examine a woman's cervix and vagina using a special microscope called a colposcope. Colposcopy is used to check for precancerous or abnormal areas.



This colposcopic view of the cervix reveals CIN 2 dysplasia, or abnormal growth of cells. This is the second stage in the development of cervical cancer. *(Custom Medical Stock Photo, Inc.)*



A colposcopy makes it possible for a physician to view this healthy cervix without surgery. *(Custom Medical Stock Photo, Inc.)*

Purpose

Colposcopy is used to identify or rule out the existence of any precancerous conditions in the cervical tissue. If a Papanicolaou (Pap) test shows abnormal cell growth, colposcopy is usually the first follow-up test performed. The physician will attempt to find the area that produced the abnormal cells and remove a sample of it for further study (biopsy) and diagnosis.

Colposcopy may also be performed if the cervix looks abnormal during a routine examination. It may be suggested for women with **genital warts** and for diethylstilbestrol (DES) daughters (women whose mothers took the anti-miscarriage drug DES when pregnant with them). Colposcopy is used in the emergency department to examine victims of sexual assault and **abuse** and document any physical evidence of vaginal injury.

Demographics

Cervical cancer affects millions of women worldwide. In the United States, the routine use of Pap tests has substantially decreased the rate of this cancer. With the introduction of a vaccine against the family of viruses associated with cervical cancer, the rate in the developed world is expected to continue to fall. Cervical cancer continues to be a major health problem for women in the developing world. Even in the United States, it is estimated that about one-third of women fail to follow up with colposcopy after an abnormal **Pap test**. Minority women, teenagers, and those of low socioeconomic status are the least likely to follow up.

Description

Colposcopy may be performed by a gynecologist or other qualified health care provider in an outpatient setting. A gynecologist specializes in the areas of women's general health, **pregnancy**, labor and **childbirth**, prenatal testing, and genetics. In cases of sexual assault, a nurse practitioner, or registered nurse may perform the procedure. If a biopsy is performed, a pathologist examines the tissue samples under a powerful microscope in the laboratory and sends the results to the health care provider who, in turn, informs the patient of the results.

Colposcopy is usually performed in a physician's office and is similar to a regular gynecologic exam. An instrument called a speculum is inserted to hold the vagina open, and the gynecologist looks at the cervix and vagina using a colposcope, a low-power microscope designed to magnify the cervix 10–40 times its normal size. Most colposcopes are connected to a video monitor that displays the area of interest. Photographs are taken during the examination to document abnormal areas.

The cervix and vagina are swabbed with dilute acetic acid (vinegar). The solution highlights abnormal areas by turning them white (instead of a normal pink color). Abnormal areas can also be identified by looking for a characteristic pattern made by abnormal blood vessels.

If any abnormal areas are seen, the doctor takes a biopsy of the tissue, a common procedure that takes about 15 minutes. Several samples might be taken, depending on the size of the abnormal area. A biopsy may cause temporary discomfort and cramping, which usually go away within a few minutes. If the abnormal area appears to extend inside the cervical canal, a scraping of the canal may also be done. The biopsy results are usually available within a week.

If the tissue sample indicates abnormal growth (dysplasia) or is precancerous, and if the entire abnormal area can be seen, the doctor may destroy the tissue using one of several procedures, including ones that use high heat (diathermy), extreme cold (cryosurgery), or lasers. Another procedure, called loop electrosurgical excision (LEEP), uses low-voltage, high-frequency radio waves to excise tissue. If any of the abnormal tissue is within the cervical canal, a cone biopsy (removal of a conical section of the cervix for inspection) will be needed.

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—Removal of a sample of abnormal tissue for more extensive examination under a microscope.

Cervix—Narrow, lower end of the uterus forming the opening to the vagina.

Cryosurgery—Freezing and destroying abnormal cells.

Diathermy—Also called electrocautery, this is a procedure that heats and destroys abnormal cells.

Diethylstilbestrol (DES)—A synthetic form of estrogen that was widely prescribed to women from 1940 to 1970 to prevent complications during pregnancy, and linked to several serious birth defects and disorders of the reproductive system in daughters of women who took DES.

Dysplasia—Abnormal cellular changes that may become cancerous.

Human papillomavirus (HPV)—A family of viruses that cause common warts of the hands and feet, as well as lesions in the genital and vaginal area. More than 50 types of HPV have been identified, some of which are linked to cancerous and precancerous conditions, including cancer of the cervix. A vaccine is now available against some of these viruses.

Loop electrosurgical excision (LEEP)—A procedure that can help diagnose and treat cervical abnormalities using a thin wire loop that emits a low-voltage high-frequency radio wave that can excise tissue.

Monsel's solution—A solution used to stop bleeding.

Pap test—The common term for the Papanicolaou test, a simple smear method of removing cervical cells to screen for abnormalities that indicate cancer or a precancerous condition.

Speculum—A retractor used to separate the walls of the vagina to make visual examination easier.

Pap test

While the Pap test is an effective screening test for abnormal cell growth of the cervix, it is an inadequate diagnostic alternative to colposcopy because of the potential for false negative results (10–50%). In some instances, a repeat Pap test may be recommended before performing colposcopy (e.g., in the case of inflammation or no previous abnormal Pap test).

Preparation

Women who are pregnant or who suspect that they are pregnant must tell their doctor before the procedure begins. Pregnant women may undergo colposcopy if they have an abnormal Pap test; special precautions, however, must be taken during biopsy of the cervix. Patients who are taking blood-thinning medications such as warfarin (Coumadin) should tell their doctor before the procedure.

Patients should be instructed not to douche, use tampons, or have sexual intercourse for 24 hours before colposcopy. Patients should empty their bladder and bowels before colposcopy for comfort. Colposcopy does not require any anesthetic medication because **pain** is minimal. If a biopsy is done, there may be mild cramps or a sharp pinching when the tissue is removed. To lessen this pain, the doctor may recommend ibuprofen (Motrin, Advil) taken the night before and the morning of the procedure (no later than 30 minutes before the appointment). Patients who are pregnant or allergic to **aspirin** or ibuprofen can instead take **acetaminophen** (Tylenol).

Aftercare

If a biopsy was done, there may be a dark vaginal discharge afterwards. After the sample is removed, the doctor applies Monsel's solution to the area to stop the bleeding. When this mixes with blood, it creates a black fluid that looks like coffee grounds. This fluid may be present for a several days after the procedure. It is also normal to have some blood spotting after colposcopy. Pain-relieving medication can be taken to lessen any post-procedural cramping.

Patients should not use tampons, douche, or have sex for at least a week after the procedure or until the doctor says it is safe because of the risk of infection.

Risks

Colposcopy is a very safe procedure. Patients may have bleeding or infection after biopsy. Bleeding is usually controlled with a topical medication prescribed by the physician or health care provider. If colposcopy is performed on a pregnant patient, there is a risk of **premature labor**.

A patient should call her doctor right away if she notices any of the following symptoms:

- heavy vaginal bleeding (more than one sanitary pad an hour)

• fever, chills, or an unpleasant vaginal odor
• lower abdominal pain

Complications associated with colposcopy are extremely rare. There is a risk that the procedure will miss precancerous or cancerous tissues and thus prolong treatment until the cancer has become advanced. The American Cancer Society estimated that 12,340 new cases of cervical cancer were diagnosed in 2013, with 4,030 deaths.

Results

If visual inspection shows that the surface of the cervix is smooth and pink, this is considered normal. Areas that look abnormal may actually be normal variations; a biopsy will indicate whether the tissue is normal or abnormal.

Abnormal conditions that can be detected using colposcopy and biopsy include precancerous tissue changes (cervical dysplasia), cancer, and cervical **warts** caused by **human papillomavirus**.

Coma

Definition

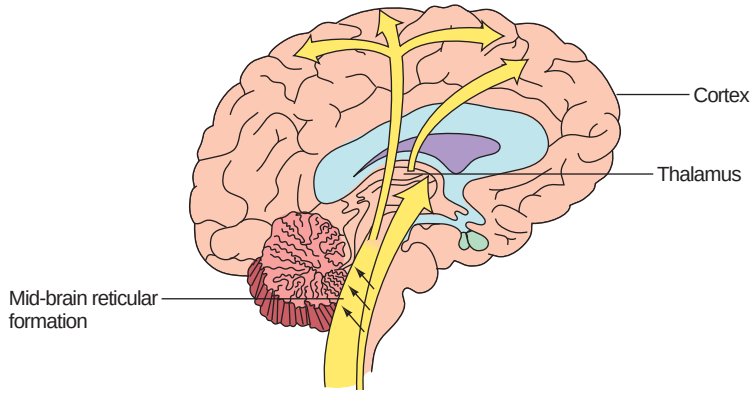
Coma, from the Greek word "koma," meaning deep sleep, is a state of extreme unresponsiveness, in which an individual exhibits no voluntary movement or behavior. Furthermore, in a deep coma, even painful stimuli (actions which, when performed on a healthy individual, result in reactions) are unable to affect any response, and normal reflexes may be lost.

Description

Coma lies on a spectrum with other alterations in consciousness. The level of consciousness required by, for example, someone reading this passage lies at one extreme end of the spectrum, while complete brain death lies at the other end of the spectrum. In between are such states as obtundation, drowsiness, and stupor. All of these are conditions which, unlike coma, still allow the individual to respond to stimuli, although such a response may be brief and require stimulus of greater than normal intensity.

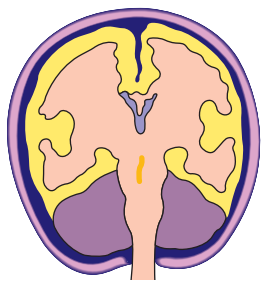
In order to understand the loss of function experienced by a comatose individual, it is necessary to first understand the important characteristics of the

WWW.BOOKBAZ.IR



A side-view of the brain, showing movement of the reticular activating substance (RAS) essential to consciousness

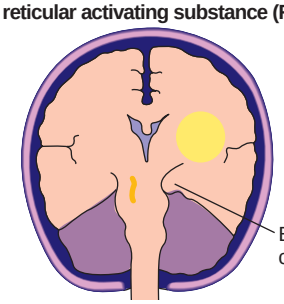
Diffuse and bilateral damage to the cerebral cortex (relative preservation of brain-stem reflexes)



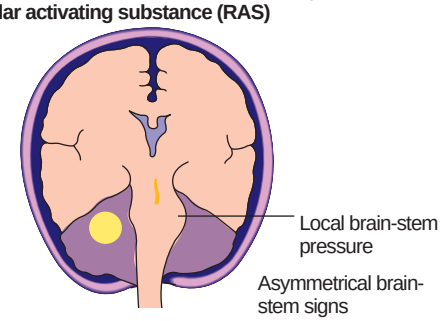
Possible causes

- Damage due to lack of oxygen or restricted blood flow, perhaps resulting from cardiac arrest, an anaesthetic accident, or shock
- Damage incurred from metabolic processes associated with kidney or liver failure, or with hypoglycemia
- Trauma damage
- Damage due to a bout with meningitis, encephalomyelitis, or a severe systemic infection

Mass lesions in this region resulting in compression of the brain-stem and damage to the reticular activating substance (RAS)

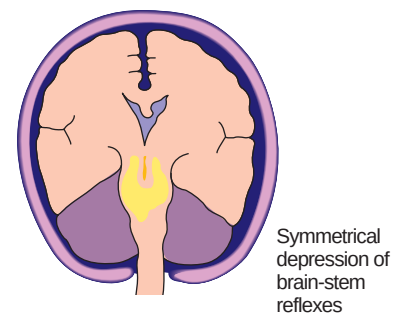


Structural lesions within this region also resulting in compression of the brain-stem and damage to the reticular activating substance (RAS)



Possible causes • Cerebellar tumors, abscesses, or hemorrhages

Lesions within the brain-stem directly suppressing the reticular activating substance (RAS)



Possible causes • Drug overdosage

The four brain conditions that result in coma. *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

conscious state. Consciousness is defined by two fundamental elements: awareness and arousal.

Awareness allows one to receive and process all the information communicated by the five senses, and thus relate to oneself and to the outside world. Awareness has both psychological and physiological components. The psychological component is governed by an individual's mind and mental processes. The physiological component refers to the functioning of an individual's brain, and therefore that brain's physical and chemical condition. Awareness is regulated by cortical areas within the cerebral hemispheres, the outermost layer of the brain that separates humans from other animals by allowing for greater intellectual functioning.

Arousal is regulated solely by physiological functioning and consists of more primitive responsiveness to the world, as demonstrated by predictable reflex (involuntary) responses to stimuli. Arousal is maintained by the reticular activating system (RAS). This is not an anatomical area of the brain, but rather a network of structures (including the brainstem, the medulla, and the thalamus) and nerve pathways, which function together to produce and maintain arousal.

Causes and symptoms

Coma, then, is the result of something that interferes with the functioning of the cerebral cortex and/or the functioning of the structures that make up the RAS. In fact, a huge and varied number of conditions can result in coma. A good way of categorizing these conditions is to consider the anatomic and the metabolic causes of coma. Anatomic causes of coma are those conditions that disrupt the normal physical architecture of the brain structures responsible for consciousness, either at the level of the cerebal cortex or the brainstem, while metabolic causes of coma consist of those conditions that change the chemical environment of the brain, thereby adversely affecting function.

There are many metabolic causes of coma, including:

- A decrease in the delivery to the brain of substances necessary for appropriate brain functioning, such as oxygen, glucose (sugar), and sodium.
- The presence of certain substances that disrupt the functioning of neurons. Drugs or alcohol in toxic quantities can result in neuronal dysfunction, as can substances normally found in the body, but that, due to some diseased state, accumulate at toxic levels. Accumulated substances that might cause coma include ammonia due to liver disease, ketones due to uncontrolled diabetes, or carbon dioxide due to a severe asthma attack.
- The changes in chemical levels in the brain due to the electrical derangements caused by seizures.

Diagnosis

As in any neurologic condition, history and examination form the cornerstone of diagnosis when the patient is in a coma; however, history must be obtained from family, friends, or EMS. The Glasgow Coma Scale is a system of examining a comatose patient. It is helpful for evaluating the depth of the coma, tracking the patient's progress, and predicting (somewhat) the ultimate outcome of the coma. The Glasgow Coma Scale assigns a different number of points for exam results in three different categories: opening the eyes, verbal response (using words or voice to respond), and motor response (moving a part of the body). Fifteen is the largest possible number of total points, indicating the highest level of functioning. The highest level of functioning would be demonstrated by an individual who spontaneously opens his/her eyes, gives appropriate answers to questions about his/her situation, and can carry out a command (such as "move your leg" or "nod your head"). Three is the least possible number of total points and would be given to a patient for whom not even a painful stimulus is sufficient to provoke a response. In the middle are those patients who may be able to respond, but who require an intense or painful stimulus, and whose response may demonstrate some degree of brain malfunctioning (such as a person whose only response to **pain** in a limb is to bend that limb in toward the body). When performed as part of the admission examination, a Glasgow score of three to five points often suggests that the patient has likely suffered fatal brain damage, while eight or more points indicates that the patient's chances for recovery are good. Expansion of the pupils and respiratory pattern are also important. Metabolic causes of coma are diagnosed from blood work and **urinalysis** to evaluate blood chemistry, drug screen, and blood cell abnormalities that may indicate infection. Anatomic causes of coma are diagnosed from CT (computed tomography) or MRI (**magnetic resonance imaging**) scans.

Treatment

Coma is a medical emergency, and attention must first be directed to maintaining the patient's respiration and circulation, using intubation and ventilation, administration of intravenous fluids or blood as needed, and other supportive care. If head trama has not been excluded, the neck should be stablized in the event of fracture. It is obviously extremely important for a physician to determine quickly the cause of a coma, so that

WWW.BOOKBAZ.IR

KEY TERMS

Anatomic—Related to the physical structure of an organ or organism.

Metabolic—Refers to the chemical processes of an organ or organism.

Neuron—The cells within the body that make up the nervous system, specifically those along which information travels.

Physiological—Pertaining to the functioning of an organ, as governed by the interactions between its physical and chemical conditions.

Psychological—Pertaining to the mind, its mental processes, and its emotional makeup.

Stimulus/stimuli—Action or actions performed on an individual that predictably provoke(s) a reaction.

potentially reversible conditions are treated immediately. For example, an infection may be treated with **antibiotics**; a **brain tumor** may be removed; and brain swelling from an injury can be reduced with certain medications. Various metabolic disorders can be addressed by supplying the individual with the correct amount of oxygen, glucose, or **sodium**; by treating the underlying disease in **liver disease**, **asthma**, or diabetes; and by halting seizures with medication. Because of their low incidence of side effects and potential for prompt reversal of coma in certain conditions, glucose, the B-vitamin thiamine, and Narcan (to counteract any narcotic-type drugs) are routinely given.

Prognosis

Some conditions that cause coma can be completely reversed, restoring the individual to his or her original level of functioning. However, if areas of the brain have been sufficiently damaged due to the severity or duration of the condition which led to the coma, the individual may recover from the coma with permanent disabilities, or may even never regain consciousness. Take, for example, the situation of someone whose coma was caused by brain injury in a car accident. Such an injury can result in one of three outcomes. In the event of a less severe brain injury, with minimal swelling, an individual may indeed recover consciousness and regain all of his or her original abilities. In the event of a more severe brain injury, with swelling that resulted in further pressure on areas of the brain, an individual may regain consciousness, but may have some degree of impairment. The impairment may be physical (such as **paralysis** of a leg) or may even result in a change in the individual's intellectual functioning and/or personality. The most severe types of brain injury, short of death, result in states in which the individual loses all ability to function and remains deeply unresponsive. An individual who has suffered such a severe brain injury may remain in a coma indefinitely. This condition is termed persistent **vegetative state**.

Outcome from a coma is therefore quite variable and depends a great deal on the cause and duration of the coma. In the case of drug poisonings, extremely high rates of recovery can be expected following prompt medical attention. Patients who have head injuries tend to do better than do patients whose coma was caused by other types of medical illnesses. Leaving out those people whose coma followed drug **poisoning**, only about 15% of patients who remain in a coma for more than just a few hours make a good recovery. Those adult patients who remain in a coma for greater than four weeks have almost no chance of eventually regaining their previous level of functioning. On the other hand, children and young adults have regained functioning even after two months in a coma.

Decongestants	Congestion Stuffy nose	Insomnia Rapid heartbeat Stimulation

(Table by PreMediaGlobal. © Cengage Learning®.)

cold, 30–50% are caused by a group known as rhinoviruses. Almost all colds clear up in less than two weeks without complications.

Description

Colds, sometimes called rhinovirus or coronavirus infections, are the most common illness to strike any part of the body. It is estimated that the average person has more than 50 colds during a lifetime. Anyone can get a cold, although pre-school and grade school children catch them more frequently than adolescents and adults. Repeated exposure to viruses causing colds creates partial immunity.

Although most colds resolve on their own without complications, they are a leading cause of visits to the doctor and of time lost from work and school. Treating symptoms of the common cold has given rise to a multi-million dollar industry in over-the-counter medications.

Cold season in the United States begins in early autumn and extends through early spring. Although it is not true that getting wet or being in a draft causes a cold (a person has to come in contact with the virus to catch a cold), certain conditions may lead to increased susceptibility. These include:

- fatigue and overwork
- emotional stress
- poor nutrition
- smoking
- living or working in crowded conditions

Colds make the upper respiratory system less resistant to bacterial infection. Secondary bacterial infection may lead to middle ear infection, **bronchitis**, **pneumonia**, sinus infection, or **strep throat**. People with chronic lung disease, **asthma**, diabetes, or a weakened immune system are more likely to develop these complications.

Causes and symptoms

Colds are caused by more than 200 different viruses. The most common groups are rhinoviruses and coronaviruses. Different groups of viruses are more infectious at different seasons of the year, but knowing the exact virus causing the cold is not important in treatment.

People with colds are contagious during the first two to four days of the infection. Colds pass from person to person in several ways. When an infected person coughs, sneezes, or speaks, tiny fluid droplets containing the virus are expelled. If these are breathed in by other people, the virus may establish itself in their noses and airways.

Colds may also be passed through direct contact. If a person with a cold touches his runny nose or watery eyes, then shakes hands with another person some of the virus is transferred to the uninfected person. If that person then touches his mouth, nose, or eyes, the virus is transferred to an environment where it can reproduce and cause a cold.

Finally, cold viruses can be spread through inanimate objects (door knobs, telephones, toys) that become contaminated with the virus. This is a common method of transmission in child care centers. If a child with a cold touches her runny nose, then plays with a toy, some of the virus may be transferred to the toy. When another child plays with the toy a short time later, he may pick up some of the virus on his hands. The second child then touches his contaminated hands to his eyes, nose, or mouth and transfers some of the cold virus to himself.

Once acquired, the cold virus attaches itself to the lining of the nasal passages and sinuses. This causes the infected cells to release a chemical called histamine. Histamine increases the blood flow to the infected cells, causing swelling, congestion, and increased mucus production. Within one to three days the infected person begins to show cold symptoms.

The first cold symptoms are a tickle in the throat, runny nose, and sneezing. The initial discharge from the nose is clear and thin. Later it changes to a thick yellow or greenish discharge. Most adults do not develop a **fever** when they catch a cold. Young children may develop a low fever of up to 102°F (38.9°C).

In addition to a runny nose and fever, signs of a cold include coughing, sneezing, nasal congestion, **headache**, muscle ache, chills, **sore throat**, hoarseness,

WWW.BOOKBAZ.IR

watery eyes, tiredness, and lack of appetite. The **cough** that accompanies a cold is usually intermittent and dry.

Most people begin to feel better four to five days after their cold symptoms become noticeable. All symptoms are generally gone within ten days, except for a dry cough that may linger for up to three weeks.

Colds make people more susceptible to bacterial infections such as strep throat, middle ear infections, and sinus infections. A person whose cold does not begin to improve within a week; or who experiences chest **pain**, fever for more than a few days, difficulty breathing, bluish lips or fingernails, a cough that brings up greenish-yellow or grayish sputum, skin rash, **swollen glands**, or whitish spots on the tonsils or throat should consult a doctor to see if he or she has acquired a secondary bacterial infection that needs to be treated with an antibiotic.

People who have **emphysema**, chronic lung disease, diabetes, or a weakened immune system—either from diseases such as **AIDS** or leukemia, or as the result of medications, (**corticosteroids**, **chemotherapy** drugs)—should consult their doctor if they get a cold. People with these health problems are more likely to get a secondary infection.

Diagnosis

Colds are diagnosed by observing a person's symptoms. There are no laboratory tests readily available to detect the cold virus. However, a doctor may do a **throat culture** or blood test to rule out a secondary infection.

Influenza is sometimes confused with a cold, but flu causes much more severe symptoms and generally a fever. **Allergies** to molds or pollens also can make the nose run. Allergies are usually more persistent than the common cold. An allergist can do tests to determine if the cold-like symptoms are being caused by an allergic reaction. Also, some people get a runny nose when they go outside in winter and breathe cold air. This type of runny nose is not a symptom of a cold.

Treatment

There are no medicines that will cure the common cold. Given time, the body's immune system will make antibodies to fight the infection, and the cold will be resolved without any intervention. **Antibiotics** are useless against a cold. However, a great deal of money is spent by pharmaceutical companies in the United States promoting products designed to relieve cold symptoms. These products usually contain **antihistamines**, **decongestants**, and/or pain relievers.

Antihistamines block the action of the chemical histamine that is produced when the cold virus invades the cells lining the nasal passages. Histamine increases blood flow and causes the cells to swell. Antihistamines are taken to relieve the symptoms of sneezing, runny nose, itchy eyes, and congestion. Side effects are **dry mouth** and drowsiness, especially with the first few doses. Antihistamines should not be taken by people who are driving or operating dangerous equipment. Some people have allergic reactions to antihistamines. Common over-the-counter antihistamines include Chlor-Trimeton, Dimetapp, Tavist, and Actifed. The generic name for two common antihistamines are chlorpheniramine and diphenhydramine.

Decongestants work to constrict the blood flow to the vessels in the nose. This can shrink the tissue, reduce congestion, and open inflamed nasal passages, making breathing easier. Decongestants can make people feel jittery or keep them from sleeping. They should not be used by people with **heart disease**, high blood pressure, or **glaucoma**. Some common decongestants are Neo-Synepherine, Novafed, and Sudafed. The generic names of common decongestants include phenylephrine, phenylpropanolamine, pseudoephedrine, and in nasal sprays naphazoline, oxymetazoline, and xylometazoline.

Many over-the-counter medications are combinations of both antihistamines and decongestants; an ache and pain reliever, such as **acetaminophen** (Datril, Tylenol, Panadol) or ibuprofen (Advil, Nuprin, Motrin, Medipren); and a cough suppressant (dextromethorphan). Common combination medications include Tylenol Cold and Flu, Triaminic, Sudafed Plus, and Tavist D. **Aspirin** should not be given to children with a cold because of its association with a risk of Reye's syndrome, a serious disease.

Nasal sprays and nose drops are other products promoted for reducing nasal congestion. These usually contain a decongestant, but the decongestant can act more quickly and strongly than ones found in pills or liquids because it is applied directly in the nose. Congestion returns after a few hours.

People can become dependent on nasal sprays and nose drops. If used for a long time, users may suffer withdrawal symptoms when these products are discontinued. Nasal sprays and nose drops should not be used for more than a few days. The label lists recommendations on length and frequency of use.

Scientists reported in 2004 the possibility of a new oral drug for use in relieving common cold symptoms. Called pleconaril, it inhibited viral replication in at least 90% of rhinoviruses if taken within 24 hours of onset.

People react differently to different cold medications and may find some more helpful than others. A medication may be effective initially, then lose some of its effectiveness. Children sometimes react differently than adults. Over-the-counter cold remedies should not be given to infants without consulting a doctor first.

Care should be taken not to exceed the recommended dosages, especially when combination medications or nasal sprays are taken. Individuals should determine whether they wish to use any of these drugs. None of them shorten or cure a cold. At best they help a person feel more comfortable. People who are confused about the drugs in any over-the-counter cold remedies should ask their pharmacist for an explanation.

In addition to the optional use of over the counter cold remedies, there are some self-care steps that people can take to ease their discomfort. These include:

- drinking plenty of fluids, but avoiding acidic juices, which may irritate the throat
- gargling with warm salt water—made by adding one teaspoon of salt to 8 oz of water—for a sore throat
- not smoking
- getting plenty of rest
- using a cool-mist room humidifier to ease congestion and sore throat
- rubbing Vaseline or other lubricant under the nose to prevent irritation from frequent nose blowing
- for babies too young to blow their noses, the mucus should be suctioned gently with an infant nasal aspirator. It may be necessary to soften the mucus first with a few drops of salt water

Alternatives

Alternative practitioners emphasize that people get colds because their immune systems are weak. They point out that everyone is exposed to cold viruses, but not everyone gets every cold. The difference seems to be in the ability of the immune system to fight infection. Prevention focuses on strengthening the immune system by eating a healthy diet low in sugars and high in fresh fruits and vegetables, practicing **meditation** to reduce **stress**, and getting regular moderate **exercise**.

Once cold symptoms appear, some naturopathic practitioners believe the symptoms should be allowed to run their course without interference. Others suggest the following:

- Inhaling a steaming mixture of lemon oil, thyme oil, eucalyptus, and tea tree oil (*Melaleuca* spp.). (Aromatherapy)
- Gargling with a mixture of water, salt, and turmeric powder or astringents such as alum, sumac, sage, and bayberry to ease a sore throat. (Ayurvedic medicine)
- Taking coneflower or goldenseal (*Hydrastis canadensis*). Other useful herbs to reduce symptoms include yarrow (*Achillea millefolium*), eyebright (*Euphrasia officinalis*), garlic (*Allium sativum*), and onions (*Allium cepa*). (Herbal)
- Microdoses of *Viscue album*, *Natrum muriaticum*, *Allium cepa*, or *Nux vomica*. (Homeopathy)
- Taking yin chiao (sometimes transliterated as yinquiao) tablets that contain honeysuckle and forsythia when symptoms appear. Natural herb loquat syrup for cough and sinus congestion and Chinese ephedra (*ma-huang*) for runny nose. (Chinese traditional medicine)
- The use of zinc lozenges every two hours along with high doses of vitamin C is suggested. Some practitioners also suggest eliminating dairy products for the duration of the cold. (Nutritional therapy)

The use of zinc lozenges may be moving toward acceptance by practitioners of traditional medicine. In 1996 the Cleveland Clinic tested zinc gluconate lozenges and found using zinc in the first 24 hours after cold symptoms occurred shortened the duration of symptoms. The mechanism by which zinc worked was not clear, but additional studies are underway.

At one time, the herb (*Echinacea* spp.) was touted as a remedy to relieve cold symptoms. However, a study published in 2004 reported that the herb failed to relieve cold symptoms in 400 children taking it and caused skin **rashes** in some children.

Prognosis

Given time, the body will make antibodies to cure itself of a cold. Most colds last a week to 10 days. Most people start feeling better within four or five days. Occasionally a cold will lead to a secondary bacterial infection that causes strep throat, bronchitis, pneumonia, sinus infection, or a middle ear infection. These conditions usually clear up rapidly when treated with an antibiotic.

Prevention

It is not possible to prevent colds because the viruses that cause colds are common and highly infectious. However, there are some steps individuals can take to reduce their spread. These include:

- washing hands well and frequently, especially after touching the nose or before handling food
- covering the mouth and nose when sneezing

WWW.BOOKBAZ.IR

KEY TERMS

Bronchial tubes—The major airways to the lungs and their main branches.

Coronavirus—A genus of viruses that cause respiratory disease and gastroenteritis.

Corticosteroids—A group of hormones produced naturally by the adrenal gland or manufactured synthetically. They are often used to treat inflammation. Examples include cortisone and prednisone.

Eustachian tube—A thin tube between the middle ear and the pharynx. Its purpose is to equalize pressure on either side of the eardrum.

Rhinovirus—A virus that infects the upper respiratory system and causes the common cold.

- disposing of used tissues properly
- avoiding close contact with someone who has a cold during the first two to four days of their infection
- not sharing food, eating utensils, or cups with anyone
- avoiding crowded places where cold germs can spread
- eating a healthy diet and getting adequate sleep

Common variable immunodeficiency

Definition

Common variable **immunodeficiency** is an immunodeficiency disorder characterized by a low level of antibodies. Patients with this disease are subject to recurring infections.

Description

Immunodeficiency means that the immune system is deficient in one or more of its components and is unable to respond effectively. Common variable immunodeficiency is the most common of the immunodeficiency disorders. Patients with this disease have frequent infections, especially those caused by the same microorganism. Recurring infections are an indication that the immune system is not responding normally and developing immunity to reinfection. Patients with common variable immunodeficiency have a normal number of B cells, the lymphocytes that make antibodies. In approximately one-third of these patients, the number of B cells in the blood that have IgG antibodies on their surface is lower than normal, but there are normal numbers of B cells in their bone marrow. B cells with IgG antibodies on their surface are capable of responding to microorganisms. The lack of IgG on the surface of the B cells means that they are not prepared to fight infection. The T-cell lymphocytes, those cells responsible for cellular immunity, are usually normal, although some cell signal components may be lacking.

Causes and symptoms

The cause of common variable immunodeficiency is not known, although some forms seem to be hereditary. The main symptom is recurring infections that tend to be chronic rather than acute. Patients may develop **diarrhea** and, as a consequence of the diarrhea, do not absorb food efficiently. This can lead to malnourishment that can aggravate the disorder. Common variable immunodeficiency normally appears in children after the age of 10. **Autoimmune disorders** such as **rheumatoid arthritis**, **thyroiditis**, and **systemic lupus erythematosus** and certain cancers such as lymphomas and leukemias may be associated with common variable immunodeficiency.

Diagnosis

As is true of most immunodeficiency disorders, one of the first signs that the patient has the condition is recurrent infections. Patients with common variable immunodeficiency are subject to recurrent infections, especially those caused by microbes that do not normally cause disease.

Tests

The main diagnostic test that distinguishes common variable immunodeficiency from other immunodeficiency diseases is the low antibody level despite the normal number of B cells. Antibody levels are tested in the serum by a procedure called electrophoresis. This procedure both quantifies the amount of antibody present and identifies the various classes

KEY TERMS

Antibodies—Molecules (immunoglobulins) produced by the immune system in response to the presence of a specific molecular trigger (antigen). Specific antibodies found in the blood or body tissues indicates that the corresponding antigen is present in the body.

Antigen—Part of an invading microorganism, which causes tissue damage and stimulates the body's immune system to produce antibodies.

Autoimmune disorder—A disorder in which the body's antibodies mistake the body's own tissues for foreign invaders. The immune system then attacks and causes damage to these tissues.

Immune globulin—A type of amino acid protein present in human serum.

Immune system—The system of the body responsible for producing various cells and chemicals that fight off infection by viruses, bacteria, fungi, and other foreign bodies. In autoimmune disease, these cells and chemicals are turned against the body itself.

of antibodies. The main class of antibody for fighting infectious diseases is IgG.

Treatment

There is no treatment that will cure the disorder. Treatment for common variable immunodeficiency aims at boosting the body's immune response and preventing or controlling infections. Immune serum, obtained from donated blood, is given as a source of antibodies to boost the immune response. Immune serum is obtained from donated blood. It contains whatever antibodies the donors had in their blood. Consequently, it may not contain all the antibodies the patient needs and may lack antibodies specific for some of the recurring infections these patients develop. **Antibiotics** are used routinely at the first sign of an infection to help the patient eliminate infectious microorganisms.

Prognosis

With good medical care, people with common variable immunodeficiency usually have a normal life span.

Prevention

The disease itself cannot be prevented, but patients and their families can take precautions to prevent the recurrent infections commonly associated with it. For example, good hygiene and **nutrition** are important, as is avoiding crowds or other people who have active infections.

Compartment syndrome

Definition

Compartment syndrome is a painful condition caused by increased pressure within the limited space of a muscle compartment. This can impede blood flow and lead to muscle and nerve damage. Acute compartment syndrome is a life-threatening medical emergency. Chronic exertional compartment syndrome (CECS) is an exercise-induced condition that subsides when the activity is stopped.

Description

Muscle groups in the arms and legs are separated by tough, thick membranes of connective tissue called

WWW.BOOKBAZ.IR

A fasciotomy was used to relieve tension and restore loss of circulation for compartment syndrome. *(B. Slaven / Custom Medical Stock)*

fasciae. Compartments are the confined spaces inside each fascia. Inside the compartments are muscle tissue, blood vessels, and nerves that are held in place by the fasciae, similar to insulation covering wire. Working against the tough fasciae creates pressure that enables the muscles to function like pumps. However, because fasciae do not stretch or expand very much, bleeding or swelling inside a compartment increases pressure on the muscles, nerves, and blood vessels. If the pressure becomes too high, blood flow into the compartment is blocked, preventing oxygen and nutrients from reaching the muscle and nerves. If the pressure is not relieved, the tissues can die, and the arm or leg may have to be amputated.

Compartment syndrome most often occurs in a forearm or one of the four compartments of the lower leg between the knee and ankle. About 5% of tibia **fractures** result in acute compartment syndrome. Compartment syndrome can also affect the thigh, upper arm, hands, feet, or buttocks. Acute compartment syndrome requires immediate emergency treatment to relieve the pressure and prevent permanent tissue damage and death. Permanent nerve injury can occur within 12–24 hours. Chronic compartment syndrome or exercise-induced compartment syndrome (CECS) is usually not a medical emergency. It most often affects a muscle compartment in the leg. In addition to the abdomen, compartment syndrome can occur (rarely) in the eye socket or orbital cavity.

In November of 2013, Denver Broncos safety Rahim Moore nearly lost his lower leg—and his life—to acute lateral compartment syndrome. He underwent emergency surgery to release the pressure and clean out dead and dying muscle. Just a few months later, in February of 2014, veteran CNN and PBS science correspondent Miles O'Brien lost his left arm to acute compartment syndrome. While reporting for the *PBS NewsHour*, a heavy crate of camera gear fell on his left arm. He worked on through the soreness until swelling and **pain** forced him to the hospital for an emergency **fasciotomy** to relieve the pressure. Complications during surgery forced the doctor to amputate his arm just above the elbow to save his life.

Demographics

The true incidence of both acute compartment syndrome and CECS is unclear. Fracture of the tibia—the inner, larger bone of the lower leg—is the most common cause of acute compartment syndrome and appears to account for 2–12% of all cases, especially fractures with associated vascular injury. Acute compartment syndrome is common in warfare, natural

disasters such as earthquakes, and other traumas such as automobile accidents. CECS usually occurs in well-conditioned athletes. Both acute compartment syndrome and CECS are more likely in males under age 40. As people age, they lose muscle mass, so there is more space within the compartments for swelling. One U.S. study found CECS in 14% of people complaining of lower leg pain. Although males and females appear to be equally affected, it has been suggested that women are more susceptible than men to CECS in the lower leg.

Compartment syndrome of the abdomen is a relatively new diagnosis and is considered rare. However, abdominal compartment syndrome appears to affect about 1% of patients admitted to the hospital for general **trauma** and 5–15% of trauma patients admitted to intensive care units.

Causes and symptoms

Causes

Acute compartment syndrome usually develops because of swelling in a compartment after severe traumatic injury, such as a complex fracture, a crushing injury, a soft-tissue injury, or surgery. It develops only rarely after relatively minor injury, although a badly bruised muscle, as from a football injury, can lead to compartment syndrome. It can develop after surgical reestablishment of blood flow in a damaged blood vessel that has been blocked for several hours. It can also develop after reestablishment of blood flow in a vessel blocked during sleep or from prolonged lying in one position; however, since sleeping people normally move when blood flow in a limb is blocked, this usually only occurs in cases of severe alcohol or drug intoxication or in people with neurological problems. Acute orbital compartment syndrome occurs from increased pressure in the orbital space, usually following facial trauma or surgery. Other conditions that can give rise to acute compartment syndrome include:

- vascular injury
- a cast or very tight restrictive bandage
- bleeding disorders
- thrombosis—a blood clot within a blood vessel
- inflammation of the fascia (fasciitis)
- gangrene
- rhabdomyolysis—muscle breakdown
- prolonged compression of a limb
- cellulitis—inflammation of connective tissue
- nephrotic syndrome—a kidney disorder

CECS is caused by **exercise**, particularly repetitive-motion activities such as running, biking, or swimming. The exercise increases blood flow to the working muscles, causing them to expand; CECS develops if the fascia does not stretch accordingly. Pressure in the compartment only increases during the particular activity and then subsides. Possible specific causes of CECS include:

- biomechanics—the way an athlete moves
- enlarged muscles
- a particularly thick or inelastic fascia
- high pressure in the veins (venous hypertension)

Symptoms

The characteristic sign of acute compartment syndrome is intense pain—pain more severe than would be expected from the injury alone—especially when the muscle is used or stretched. The pain is not relieved by medication or by raising the affected area. Other symptoms may include tingling or burning in the skin or a tight or full feeling in the muscle. Decreased sensation, skin paleness, weakness, or severe pain that worsens is characteristic of more severe cases. Numbness or **paralysis** is a late stage that usually indicates permanent muscle damage.

Symptoms of CECS are cramping, aching, or burning pain during exercise, usually in the lower leg, that subsides when the activity stops. Typically, the pain begins soon after starting exercise and progressively worsens, disappearing within 30 minutes after stopping the exercise. However over time, the pain may persist longer after exercise, possibly up to one or two days. Other symptoms can include swelling, numbness, or tingling in the limb; tightness in the limb; difficulty moving the foot or foot drop in severe cases when nerves are affected; or visible bulging or swelling from a muscle **hernia**. CECS occasionally becomes disabling. It is sometimes mistaken for **shin splints**, which commonly cause leg pain in young people performing weight-bearing exercise such as running. Shin splints that do not improve with self-care may indicate CECS.

Risk factors

Acute compartment syndrome is usually the result of accidental injury. The major risk factor for CECS is participation in sports involving repetitive impact, such as fast walking and running. Other factors increase the risk of CECS:

- Age: Although people of any age can develop CECS, it is most common in athletes under 30.

WWW.BOOKBAZ.IR

- Overtraining: Workouts that are too intense or too frequent are risk factors.
- Anabolic steroids or creatine supplements: These substances can increase water content and mass of a muscle, which are risk factors for CECS.
- Significant increase in training: Athletes who train very hard despite having CECS can worsen the condition.
- Sudden, rigorous training by physically inactive individuals: People who are not in condition and train very hard put themselves at risk for this condition.

Diagnosis

Examination

Acute compartment syndrome requires immediate treatment in an emergency department. Diagnosis is based on the following:

- pain out of proportion to the injury
- severe pain with passive stretching, such as moving the toes in the case of lower-leg compartment syndrome
- limb paleness from lack of blood flow
- change in or loss of pulse in the limb
- burning or prickling sensation—numbness or tingling indicates that the nerve is dying, and complete numbness and weakness may mean that the limb cannot be saved

Diagnosis of CECS requires ruling out more common conditions such as shin splints or stress fractures. The doctor will ask about symptoms and may press on the tendons to check for tendonitis. Since the physical exam may appear normal, it may be repeated after the patient has exercised and when a bulging (herniated) muscle, tension, or tenderness may be apparent. The patient may be referred to a sports medicine specialist or orthopedic surgeon.

Acute orbital compartment syndrome is readily diagnosed by a **physical examination** and progressive visual loss. Prompt treatment may prevent blindness.

Tests

Compartment syndrome can be confirmed by directly measuring the compartment pressure with the insertion of a needle connected to a pressure meter. For CECS, the test may be performed during and after activity that causes pain. However, because the test is invasive and mildly painful, it is not usually performed unless there are strong indications of CECS.

KEY TERMS

Chronic exertional compartment syndrome (CECS)—Compartment syndrome that develops during exercise and subsides when the activity is halted.

Compartment—A muscle group and its accompanying nerves and blood vessels that are contained within the fascia.

Fascia—A sheet of connective tissue that covers or binds together an anatomical structure such as muscle.

Fasciectomy—Surgical removal of strips of fascia to relieve pressure in the compartment.

Fasciotomy—Surgical incision of a fascia to relieve pressure in the compartment.

Magnetic resonance imaging (MRI)—A diagnostic technique that provides cross-sectional images of organs or structures within the body.

Near-infrared spectroscopy (NIRS)—A diagnostic technique for measuring oxygen saturation in tissues.

Orbital compartment syndrome—Compartment syndrome in the eye socket.

Rhabdomyolysis—The rapid breakdown of skeletal muscle and release into the blood of muscle cell contents.

Shin splints—Painful injury and inflammation of the tibia and toe extensor muscles or their fasciae from repeated minor trauma such as running on a hard surface.

Stress fracture—A hairline fracture in a bone, usually in the foot or lower leg, from repeated stress.

Procedures

For CECS, x rays may be used to rule out a stress fracture. Other studies, such as **magnetic resonance imaging** (MRI) or near-infrared spectroscopy (NIRS), may also be performed. MRI can visualize the structure of the muscles in the compartment to rule out other causes for the pain. NIRS measures tissue oxygen saturation with light to determine whether the muscle compartment has decreased blood flow.

Treatment

Traditional

Acute compartment syndrome is treated with emergency surgery called fasciotomy, in which a long incision is made through the skin and fascia over the

affected compartment to relieve the pressure. If the swelling in the compartment is severe, the incision may not be repaired until after swelling subsides: The wound is covered with a sterile dressing and closed in a second surgery 48–72 hours later. Sometimes a skin graft is used to close the wound.

Surgery is also the primary and most effective treatment for CECS, although more conservative treatment may be attempted first. The surgery is either a fasciotomy or a fasciectomy, in which part of the fascia is removed. This gives the compartment room to expand under future increased pressure.

Therapy

CECS may be treated with **physical therapy** or orthotic inserts for shoes, although these are of questionable benefit.

Drugs

Pain relievers, such as ibuprofen or **acetaminophen**, may provide temporary relief for CECS. Anti-inflammatory medications are sometimes suggested but are of questionable benefit.

Alternatives

If compartment syndrome is caused by a cast or constricting bandage, the cast or bandage can be removed or loosened. Stretching or strengthening routines or massage may be helpful for CECS, although they do not usually provide lasting relief.

Home remedies

The most common treatments for CECS are temporarily discontinuing exercise, switching to a different sport—such as biking, swimming, or other low-impact activity instead of jogging—or trying different biomechanical techniques, such as changing the way one lands when jogging. However, the symptoms usually return when the earlier sport or technique is resumed. Some athletes find some relief from changing surfaces, such as running on a track instead of concrete or performing on grass instead of artificial turf. Icing the area may bring temporary relief, but athletes should never continue exercising through the pain, since this can lead to permanent muscle or nerve damage.

Prognosis

Prognosis for acute compartment syndrome depends on the cause. With immediate diagnosis and treatment, the muscles and nerves in the compartment usually recover. However, delayed treatment can result in permanent nerve injury and loss of muscle function. Treatment is most often delayed because the patient is unconscious or heavily sedated and is unaware of the pain. Acute compartment syndrome in multiple areas of the body—as can happen in an accident or earthquake—may be fatal.

Possible surgical complications include infection, permanent nerve damage, numbness, or scarring. However, surgery for CESH is often successful, enabling athletes to return to their sport of choice.

Prevention

Compartment syndrome is unlikely to be preventable, although early diagnosis and treatment helps prevent complications. Anyone with a cast should be aware of the risk of swelling and seek emergency assistance if pain increases despite pain medication and elevating the area. Surgeons treating vascular trauma or injury often perform prophylactic fasciotomy during vascular repair if the patient is at risk for compartment syndrome.

Although there are no specific measures for preventing CECS, basic sports guidelines are important:

- warming up before exercising and cooling down afterwards
- stopping exercise if pain develops
- consulting a doctor before starting a new exercise regimen
- staying hydrated
- eating a healthy, balanced diet
- participating in a variety of exercises

Complement deficiencies

Definition

Complement deficiencies are a group of disorders in which there is a reduced level of specific proteins, complement, involved in proper immune functioning.

Description

Complement plays several functions in immunity. It can poke holes in bacteria, kill bacteria that are first targeted by antibodies, or, working with antibodies, point out which bacteria need to be engulfed by white blood cells. Without sufficient complement, the body is prone to frequent infections, like **pneumonia** or **meningitis**, or other illnesses, including autoimmune diseases, like **systemic lupus erythematosus**. Since there are more than 20 different types of complement, the disease that results depends on the specific complement that is lacking.

Cause and symptoms

A defect in the complement system can be genetic, but a secondary complement deficiency can also result from ailments that involve a lot of protein loss, including serious **burns**, liver or **kidney disease**, and autoimmune diseases, like lupus. Symptoms vary depending on the specific complement deficiency and the disease that results. Some people remain healthy with no symptoms at all. Others, who suffer from frequent infections, may develop a high **fever**, **diarrhea**, headaches with a stiff neck, or a **cough** with chest **pain**. If an autoimmune disease develops, like lupus, the person may lose weight, suffer from a rash, and have joint pain. Other symptoms of complement deficiency diseases (like hereditary angioedema, paroxysmal nocturnal hemoglobinuria, or leukocyte adhesion deficiency syndrome) include abdominal and back pain, skin infections, **edema** or swelling of the face, and red bumps on the skin.

Diagnosis

There are blood tests that determine the activity of the complement system. The two most common screening tests, CH50 and APH50, tell the physician which group of complement components have a defect. More specific blood tests for the individual complement components (e.g., C3 or C4 complement) are then performed. Other specialized blood tests, including C1 esterase level, Ham test, and a white blood count, may also be performed.

Treatment

There is no way to treat the actual complement deficiency. However, **antibiotics** are used to treat infections and vaccinations are given to reduce the risk of disease. Often, the person is vaccinated against infections that include **influenza**, pneumonia, and meningitis. In some cases, (e.g. a specific disease called paroxysmal nocturnal hemoglobinuria [NH]) a bone marrow transplant may be recommended.

Prognosis

Since complement deficiencies include a wide range of disorders, the prognoses can also vary widely. Some patients remain healthy their entire life. Others are hospitalized frequently because of infections which, if not properly treated, can be fatal. Those

KEY TERMS

Autoimmune diseases—A group of diseases, like rheumatoid arthritis and systemic lupus erythematosus, in which immune cells turn on the body, attacking various tissues and organs.

Hereditary angioedema—A complement deficiency characterized by lymphatic vessel blockages that cause temporary swelling (edema) of areas of the skin, mucous membranes, and, sometimes, internal organs.

Leukocyte adhesion deficiency syndrome—A complement deficiency syndrome characterized by recurrent infections of the skin, mucous membranes, and gastrointestinal tract and the absence of pus formation. This disorder is sometimes apparent at birth when separation of the umbilical cord takes longer than normal.

Meningitis—An inflammation of the lining surrounding the brain and spinal cord.

Paroxysmal nocturnal hemoglobinuria (PNH)—A rare complement disorder characterized by episodes of red blood cell destruction (hemolysis) and blood in the urine (hemoglobinuria) that is worse at night.

Systemic lupus erythematosus—An autoimmune disease in which the immune system attacks the body's connective tissue. A butterfly-shaped facial rash is characteristic.

White blood cells—Cells that are key in immune defense. There are various types, including those that engulf and kill invading bacteria.

with autoimmune diseases could have a normal life expectancy. There are some complement deficiencies, that have a high mortality rate. In those cases, death may occur within 10 years after diagnosis.

Prevention

There is currently no way to prevent complement deficiencies.

Complete blood count

Definition

A complete blood count (CBC) provides important information about the types and numbers of cells in the blood; in particular, information about red blood cells, white blood cells and platelets.

Purpose

The purpose of a CBC is to help physicians to diagnose conditions related to abnormalities in the blood such as infections and anemia.

Description

A complete blood count usually includes the following elements:

- red blood cell count (also called RBC or erythrocyte count)
- red blood cell indices—mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC)
- hemoglobin (also called Hgb)
- hematocrit (also called HCT)
- white blood cell count (also called WBC or leukocyte count)
- platelet count (also called thrombocyte count)

Red blood cells (erythrocytes) transport oxygen between the lungs and cells throughout the rest of the body. They also transport carbon dioxide back to the lungs so it can be exhaled. A low red cell count may be due to anemia and cells in the body may not be getting the oxygen that they need. A red blood cell count that is abnormally high may be due to an uncommon condition called polycythemia.

White blood cells (leukocytes) protect the body against infection. When an infection develops, white blood cells attack and destroy the pathogen (bacteria, virus, or other organism) causing it. White blood cells

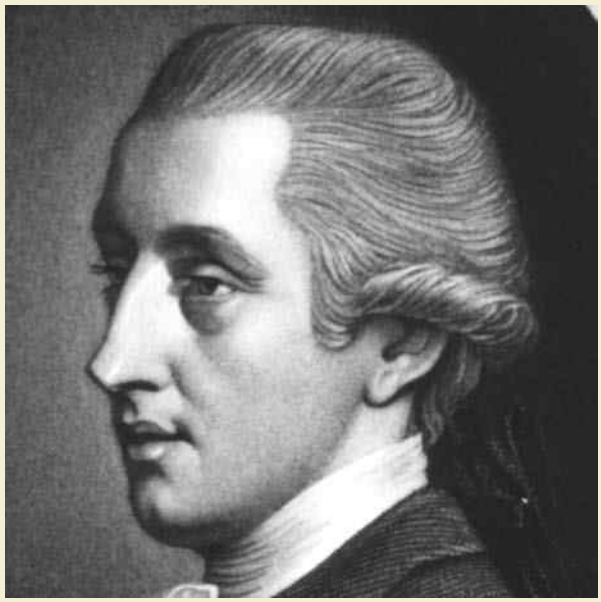
WILLIAM HEWSON AND THE ISOLATION OF FIBRINOGEN



William Hewson *(Courtesy of National Library of Medicine)*

William Hewson (1739–1774), known as the father of haematology, was a leading scientist of his time in many areas and is credited with the discovery of fibrinogen and its role in clotting.

Hewson was born in Hexham, Northumberland, England, to a country surgeon. He was one of eleven children. He chose to follow in his father's footsteps and pursue medicine, first training with his father and then with another surgeon in Newcastle.

Hewson was well connected to the other preeminent medical minds of his time. He continued his studies by traveling to London to live with and learn from John and William Hunter, brothers who were the leading anatomists of the period. They had a medical and anatomy school, where Hewson studied, worked, and eventually also gave lectures. In addition to human anatomy, the brothers studied the anatomy of mammals and fish, a practice that Hewson continued. Over his career Hewson collected and performed dissection on many human and animal bones at his London anatomy school. The building underwent restoration in the late 1990s, and a 1998 excavation at the site unearthed the skeletal remains of ten individuals. These bones were subsequently put on public display.

In addition to his anatomy training, Hewson studied physics and midwifery; however, his interests eventually centered on the lymphatic system. He was one of the first to use a microscope to investigate blood cells. The microscopes of the time were crude and often produced distorted images. Investigation was further frustrated by the existence of very few methods of mounting specimens for examination. Hewson examined both white and red blood cells and was the first scientist to discover that red blood cells have a flat, disc-like shape, not the glob-like shape that was the accepted theory at that time. He believed that red blood cells contained a nucleus, which is not the case. What he mistook for a nucleus was a byproduct of the microscope technology available.

Hewson is best known for discovering fibrinogen, a protein produced by the liver that occurs in the blood plasma. When it is exposed to the enzyme thrombin, fibrin is formed. Fibrin is a stringy, fibrous protein that forms the scaffolding of blood clots. Before Hewson's work, scientists believed that the substances responsible for clotting blood were found in the red blood cells. Hewson, however, demonstrated that the necessary substance is actually contained in the blood plasma.

In addition to his discovery of fibrinogen, Hewson showed that certain other substances could promote clotting, that the lymphatic system is separate from the circulatory system, and that all of the major body cavities drain into the lymphatic system. Hewson died prematurely at the age of thirty-five. He injured himself while dissecting a cadaver, and the cut became septic.

are larger than red blood cells but fewer in number. When a person has a bacterial infection, the number of white cells increases very quickly. The number of white blood cells is sometimes used to pinpoint an infection or to see how the body is reacting to cancer treatment.

Platelets (thrombocytes) are the smallest type of blood cell. They are essential to the process of blood clotting. When bleeding occurs, platelets swell, clump together, and form a sticky plug that helps to stop the bleeding. If the **platelet count** is too low, uncontrolled bleeding may occur. If the platelet count is too high, there is a chance of a blood clot forming in a blood vessel. Platelets may contribute to the process of hardening of the arteries (atherosclerosis).

There are three **red blood cell indices**: mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). They are measured by a laboratory instrument machine that calculates their values from other measurements in a complete blood count. The mean corpuscular volume reflects the average size of red blood cells. The mean corpuscular hemoglobin value reflects the quantity of hemoglobin in an average red blood cell. The mean corpuscular hemoglobin

concentration reflects the concentration of hemoglobin in an average red blood cell. These numbers are used in diagnosing different types of anemia.

The hemoglobin value reflects the amount of hemoglobin in blood and is a good measure of the ability of a person's blood stream to carry oxygen throughout the body. A hemoglobin molecule comprises much of the volume of red blood cells. It carries oxygen and gives red blood cells their normal color.

The **hematocrit** value reflects the amount of space (volume) that red blood cells occupy in the blood. The value is given as a percentage of red blood cells in a volume of blood. For example, a hematocrit of 46 means that 46% of the blood's volume is comprised of red blood cells. Males and females have different normal hematocrit values.

Preparation

A complete blood count can be ordered at any time. The only preparation needed is to clean the venipuncture site with alcohol.

A complete blood count is typically ordered by a family doctor, internist, or surgeon, but any physician may order one. The blood sample is usually obtained by a nurse, phlebotomist, or medical technologist. It is tested or processed by a medical technologist. Once the results are reviewed, they are returned to the person being tested and interpreted by the physician who initially ordered the complete blood count.

Risks

The most common risks of a complete blood count are minor bleeding (hematoma) or bruising at the site of venipuncture.

Results

Normal values for the elements of a complete blood count include:

- red blood cell (erythrocyte) count: 4.2–5.9 million
- white blood cell (leukocyte) count: 4,300–10,800
- platelet (thrombocyte) count: 150,000–400,000
- mean corpuscular volume (MCV): 86–98
- mean corpuscular hemoglobin (MCH): 27–32
- mean corpuscular hemoglobin concentration (MCHC): 32–36%
- hemoglobin (Hgb): 13–18 for men and 12–16 for women
- hematocrit (HCT): 45–52% for men and 37–48% for women

Computed tomography scans

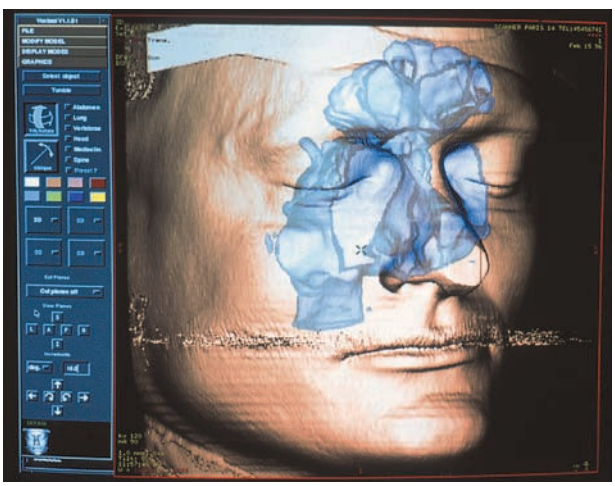
Definition

Computed tomography (CT) scans are completed with the use of a 360-degree x-ray beam and computer production of images. These scans allow for cross-sectional views of body organs and tissues.

Purpose

CT scans are used to image a wide variety of body structures and internal organs. Since the 1990s, CT equipment has become more affordable and available. In some diagnoses, CT scans have become the first imaging exam of choice. Because the computerized image is so sharp, focused, and three-dimensional, many tissues can be better differentiated than on standard x rays. Common CT indications include:

- Sinus studies. The CT scan can show details of a sinusitis, and bone fractures. Physicians may order CT of the sinuses to provide an accurate map for surgery.
- Brain studies. Brain scans can detect hematomas, tumors, and strokes. The introduction of CT scanning, especially spiral CT, has helped reduce the need for more invasive procedures such as cerebral angiography.
- Body scans. CT scans of the body will often be used to observe abdominal organs, such as the liver, kidneys, adrenal glands, spleen, and lymph nodes, and extremities.



CT scan of facial sinuses. *(Pascal Goetgheluck/Photo Researchers, Inc.)*

- Aorta scans. CT scans can focus on the thoracic or abdominal aorta to locate aneurysms and other possible aortic diseases.
- Chest scans. CT scans of the chest are useful in distinguishing tumors and in detailing accumulation of fluid in chest infections.

Precautions

Pregnant women or those who could possibly be pregnant should not have a CT scan unless the diagnostic benefits outweigh the risks. Pregnant patients should particularly avoid full body or abdominal scans. If the exam is necessary for obstetrics purposes, technologists are instructed not to repeat films if there are errors. Pregnant patients receiving CT or any x-ray exam away from the abdominal area may be protected by a lead apron; most radiation, known as scatter, travels through the body and is not blocked by the apron.

Contrast agents are often used in CT exams and the use of these agents should be discussed with the medical professional prior to the procedure. Patients should be asked to sign a consent form concerning the administration of contrast. One of the common contrast agents, iodine, can cause allergic reactions. Patients who are known to be allergic to iodine (or shellfish) should inform the physician prior to the CT scan.

Description

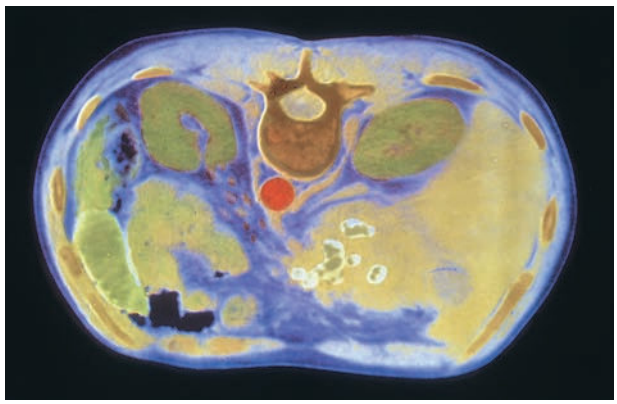
Computed tomography, also called CT scan, CAT scan, or computerized axial tomography, is a combination of focused x-ray beams and computerized production of an image. Introduced in the early 1970s, this radiologic procedure has advanced rapidly and is now widely used, sometimes in the place of standard x rays.

CT equipment

A CT scan may be performed in a hospital or outpatient imaging center. Although the equipment looks large and intimidating, it is very sophisticated and fairly comfortable. The patient is asked to lie on a gantry, or narrow table, that slides into the center of the scanner. The scanner looks like a doughnut and is round in the middle, which allows the x-ray beam to rotate around the patient. The scanner section may also be tilted slightly to allow for certain cross-sectional angles.

CT procedure

The patient will feel the gantry move very slightly as the precise adjustments for each sectional image are made. A technologist watches the procedure from a window and views the images on a computer screen.



Colorized CT scan of human abdomen—aorta is dead center in red. *(SPL/Photo Researchers, Inc.)*

It is essential that the patient lie very still during the procedure to prevent motion blurring. In some studies, such as chest CTs, the patient will be asked to hold his or her breath during image capture.

Following the procedure, films of the images are usually printed for the radiologist and referring physician to review. A radiologist can also interpret CT exams on a special computer screen. The procedure time will vary in length depending on the area being imaged. Average study times are from 30 to 60 minutes. Some patients may be concerned about claustrophobia, but the width of the "doughnut" portion of the scanner is such that many patients can be reassured of openness.

The CT image

While traditional x rays image organs in two dimensions, with the possibility that organs in the front of the body are superimposed over those in the back, CT scans allow for a more three-dimensional effect. Some have compared CT images to slices in a loaf of bread. Precise sections of the body can be located and imaged as cross-sectional views. The screen before the technologist shows a computer's analysis of each section detected by the x-ray beam. Thus, various densities of tissue can be easily distinguished.

Contrast agents

Contrast agents are often used in CT exams and in other **radiology** procedures to illuminate certain details of anatomy that may not be easily seen. Some contrasts are natural, such as air or water. Other times, a water-based contrast agent is administered for specific diagnostic purposes. Barium sulfate is commonly used in gastroenterology procedures. The patient may drink this contrast, or receive it in an enema. Oral and rectal contrast are usually given when examining the abdomen or cells, and not given when scanning the brain or chest. Iodine is the most widely used intravenous contrast agent and is given through an intravenous needle.

If contrast agents are used in the CT exam, these will be administered several minutes before the study begins. Abdominal CT patients may be asked to drink a contrast medium. Some patients may experience a salty taste, flushing of the face, warmth or slight nausea, or **hives** from an intravenous contrast injection. Technologists and radiologists have equipment and training to help patients through these minor reactions and to handle more severe reactions. Severe reactions to contrast are rare, but do occur.

Spiral CT

Spiral CT, also called helical CT, is a newer version of CT scanning which is continuous in motion and allows for three-dimensional recreation of images. For example, traditional CT allows the technologist to take slices at very small and precise intervals one after the other. Spiral CT allows for a continuous flow of images, without stopping the scanner to move to the next image slice. A major advantage of spiral CT is the ability to reconstruct images anywhere along the length of the study area. The procedure also speeds up the imaging process, meaning less time for the patient to lie still. The ability to image contrast more rapidly after it is injected, when it is at its highest level, is another advantage of spiral CT's high speed.

Some facilities will have both spiral and conventional CT available. Although spiral is more advantageous for many applications, conventional CT is still a superior and precise method for imaging many tissues and structures. The physician will evaluate which type of CT works best for the specific exam purpose.

Preparation

If a contrast medium is administered, the patient may be asked to fast about four to six hours prior to the procedure. Patients will usually be given a gown (like a typical hospital gown) to be worn during the procedure. All metal and jewelry should be removed to avoid artifacts on the film.

Aftercare

No aftercare is generally required following a CT scan. Immediately following the exam, the technologist will continue to watch the patient for possible

WWW.BOOKBAZ.IR

KEY TERMS

Aneurysm—The bulging of the blood vessel wall. Aortic aneurysms are the most dangerous. Aneurysms can break and cause bleeding.

Contrast (agent, medium)—A substance injected into the body that illuminates certain structures that would otherwise be hard to see on the radiograph (film).

Gantry—A name for the couch or table used in a CT scan. The patient lies on the gantry while it slides into the x-ray scanner portion.

Hematoma—A collection of blood that has escaped from the vessels. It may clot and harden, causing pain to the patient.

Hydrocephalus—A collection of fluid on or around the brain. The pressure from the spinal fluid causes the ventricles to widen.

Metastasis—Secondary cancer, or cancer that has spread from one body organ or tissue to another.

Radiologist—A medical doctor specially trained in radiology (x ray) interpretation and its use in the diagnosis of disease and injury.

Spiral CT—Also referred to as helical CT, this method allows for continuous 360-degree x-ray image capture.

Thoracic—Refers to the chest area. The thorax runs between the abdomen and neck and is encased in the ribs.

adverse contrast reactions. Patients are instructed to advise the technologist of any symptoms, particularly respiratory difficulty. The site of contrast injection will be bandaged and may feel tender following the exam. Hives may develop later and usually do not require treatment.

Risks

Radiation exposure from a CT scan is similar to, though higher than, that of a conventional x ray. Although this is a risk to pregnant women, the exposure to other adults is minimal and should produce no effects. Although severe contrast reactions are rare, they are a risk of many CT procedures.

Results

Normal findings on a CT exam show bone, the most dense tissue, as white areas. Tissues and fat will show as various shades of gray, and fluids will be gray or black. Air will also look black. Intravenous, oral, and rectal contrast appear as white areas. The radiologist can determine if tissues and organs appear normal by the sensitivity of the gray shadows. In CT, the images that can cut through a section of tissue or organ provide three-dimensional viewing for the radiologist and referring physician.

Abnormal results

Abnormal results may show different characteristics of tissues within organs. Accumulations of blood or other fluids where they do not belong may be detected. Radiologists can differentiate among types of tumors throughout the body by viewing details of their makeup.

Sinus studies

The increasing availability and lowered cost of CT scanning has led to its increased use in sinus studies, either as a replacement for a sinus x ray or as a follow-up to an abnormal sinus radiograph. The sensitivity of CT allows for location of areas of sinus infection, particularly chronic infection. CT scans can show the extent and location of tiny **fractures** to the sinus and nasal bones. Foreign bodies in the sinus and nasal area are also easily detected by CT. CT imaging of the sinuses is important in evaluating **trauma** or disease of the sphenoid bone (the wedge shaped bone at the base of the skull). Sinus tumors will show as shades of gray indicating the difference in their density from that of normal tissues in the area.

Brain studies

The precise differences in density allowed by CT scan can clearly show tumors, strokes, or lesions in the brain area as altered densities. These lighter or darker areas on the image may indicate a tumor or hematoma within the brain and skull area. Different types of tumors can be identified by the presence of **edema**, by the tissue's density, or by studying blood vessel location and activity. The speed and convenience of CT often allows for detection of hemorrhage before symptoms even occur. Congenital abnormalities in children, such as **hydrocephalus**, may also be confirmed with CT. Hydrocephalus is suggested by enlargement of the fluid structures called ventricles of the brain.

Body scans

The body scan can identify abnormal body structures and organs. Throughout the body, a CT may indicate tumors or cysts, enlarged lymph nodes, abnormal collections of fluids, blood or fat, and metastasis of cancer. Tumors resulting from metastasis are different in makeup than primary tumors, or those that originate in the location of study. Fractures or damage to soft tissues and ligaments will be more easily seen on the sensitive images produced by CT scanning, though CT is not usually done for these. Liver conditions, such as **cirrhosis** or abscessed or **fatty liver**, may be observed on the body scan.

CT of the aorta

CT provides the ability to see and measure the thickness of the aortal wall, which is very helpful in diagnosing aortic aneurysms. The use of contrast will help see details within the aorta. In addition, density can identify calcification, and this helps differentiate between acute and chronic problems. An abnormal CT scan may indicate signs of aortic clots. Aortic rupture is suggested by signs such as a hematoma around the aorta or the escape of blood from its cavity.

Chest scans

In addition to those findings that may indicate aortic aneurysms, chest CT studies can show other problems in the heart and lungs, and distinguish between an **aortic aneurysm** and a tumor adjacent to the aorta. The computer will not only show differences between air, water, tissues, and bone, but will also assign numerical values to the various densities. Coin-sized lesions in the lungs may be indicative of **tuberculosis** or tumors. CT will help distinguish among the two. Enlarged lymph nodes in the chest area may indicate Hodgkin's disease. Spiral CT is particularly effective at identifying pulmonary emboli (clots in the lung's blood vessels).

Concierge medicine

Definition

Concierge medicine as practiced in the United States is a relatively new form of direct health care (health care that does not involve insurance) in which the patient pays an annual fee or retainer to the physician in return for enhanced access to primary care. It does not include specialist or emergency care, which are considered forms of secondary health care. Concierge medicine may or may not involve fees for office visits in addition to the annual retainer. Other names for concierge medicine are retainer medicine, boutique medicine, private medicine, membership medicine, cash-only practice, direct care, direct primary care (DPC), intensive primary care, and direct practice medicine (DPM).

The word *concierge* itself is French and in the Middle Ages referred to a person who tended to the needs of nobles visiting another lord's castle; this officer was known as the keeper of the candles or *comte des cierges*. By the late nineteenth and early twentieth centuries, however, the French concierge was a staff member in a large hotel or apartment building who kept room keys, held mail for guests, monitored the comings and goings of visitors and repair personnel, and performed such other services as making dinner or travel reservations for patrons. The history of the word, with its overtones of elitism or snobbery, helps to explain why some physicians prefer to refer to concierge medicine as private medicine or direct care medicine.

Description

Origins

Concierge medicine first emerged in the United States in the late 1990s in the form of MD^2 ("MD Squared"), a concierge practice started in Seattle by two physicians who cared for members of the local professional basketball team. They decided to offer the same level of personal primary care—24/7 access, house calls, and easier visits to specialists—to a select group of families, limiting the practice to just 50 families rather than the 3,000–4,000 people served by most primary-care physicians in the United States. The initial charge was $25,000 per year per patient. The founders of MD^2 did not invent the term *concierge medicine*, however, preferring to refer to their practice as "highly attentive medicine."

The next stage in the evolution of concierge medicine was to lower the annual retainer in order to make

WWW.BOOKBAZ.IR

direct-pay primary care more affordable to middle-class families. The *New York Times* has referred to this development as "concierge medicine for the masses." For example, Qliance, a direct primary-care provider based in Seattle, charges between $59 and $99 per month for adult members according to age group, with lower fees for children. The monthly fee includes unlimited doctor visits, 24-hour e-mail access to the medical staff, and same-day or next-day appointments. Some concierge practices also include certain laboratory tests, basic X rays, and such minor surgical procedures as suturing small cuts. Concierge medicine does not, however, include secondary or tertiary medical care.

Concierge medicine has grown rapidly enough since the early 2000s to form its own provider organizations. In 2003 a group of concierge and other direct-pay physicians formed the Society for Innovative Medical Practice Design (SIMPD). The organization changed its name in late 2009 to the American Academy of Private Physicians (AAPP), which claims a membership of over 5,000 doctors as of mid-2014 and maintains an online directory of concierge practices. Another network is the Direct Primary Care Coalition or DPCC. A study of concierge medicine conducted in 2010 reported that 66% of concierge physicians were internists, with family practice physicians the next largest group represented. Starting in 2009, concierge pediatrics and dental practices also formed. Other primary-care practitioners in concierge practices are geriatricians (physicians who care for the elderly) and general practitioners. In 2011, *Concierge Medicine Today*, *Direct Primary Care Journal*, and other newsletters and trade journals aimed at direct-care physicians began publication, which is yet another sign that concierge medicine is attracting a growing number of American physicians.

The newest stage in the development of concierge medicine is expansion into medical tourism, or international concierge health care. American company International Medical Concierge was formed in 2012, followed by Medical Concierge Tourism International in 2013. International Medical Concierge states on its website that its services are offered not only to citizens of the United States but also to Canadians tired of the long waiting lists and healthcare rationing involved in the Canadian healthcare system.

Concierge versus direct-pay models

Concierge medicine does not have a one-size-fits-all model as of 2014. While concierge physicians in general limit the size of their practice in order to spend more time with each patient, some see as many as 1,000 patients per year, not just a select small group of families. Although some concierge practices do not accept insurance, others do—but charge an annual retainer in order to provide enhanced patient services (usually same- or next-day appointments, longer appointments, 24/7 access to the doctor, and in some cases home-based medical visits, plus highly individualized, coordinated, and comprehensive care administration). The annual retainer, however, is not a substitute for insurance and does not cover consultations with specialists, emergency health care from other physicians, prescription medications, or hospitalization.

Although concierge medicine and direct primary care (DPC) are often used as interchangeable terms, some analysts prefer to distinguish between them on the basis of the annual or monthly retainer plus increased access to the doctor (concierge medicine), versus a flat-rate cash-only fee (DPC). DPC practices charge patients a flat monthly (often as low as $50) or annual fee under terms of a contract in exchange for access to a broad range of primary care and medical administrative services as distinct from unlimited access to the doctor. What both forms of private medicine have in common is a direct relationship between the doctor and the patient as the payer.

Purpose

Concierge medicine serves several purposes in the ongoing crisis in American health care as of 2014. First, it addresses the possibility that the Affordable Care Act will actually add to the number of uninsured Americans. A survey commissioned by the Physicians Foundation in 2012 reported that 9.6% of the physicians who replied to the survey planned to convert their practices to the concierge model within the next one to three years. Significantly, the American Academy of Family Physicians (AAFP), which represents a large number of primary healthcare providers, offered an online webinar to its members in May 2013 that explained the workings of concierge and DPC practices. If the number of low-cost DPC practices continued to expand, the uninsured might be able to obtain primary care at a lower cost than the insurance offered on ACA exchanges. In addition, many Americans frustrated by the discovery that purchasing insurance through the ACA exchanges does not guarantee actual access to health care may turn to DPC practices for their medical needs.

Second, the concierge and DPC models offer physicians some relief from the growing burden of insurance paperwork. One physician told a reporter for *The Atlantic* that he spends 2–3 hours per day

outside patient care just on paperwork. Various studies have found that between 10 cents and 40 cents of every dollar spent on health care in the United States goes to cover the administrative costs involved in health insurance paperwork. The Commonwealth Fund reported in 2011 that the average American medical practice spends $83,000 per doctor per year dealing with insurers. In addition, declining reimbursements from insurance companies have meant that primary-care doctors have had to see as many patients as possible per day just to cover the expenses of running a practice. The time squeeze means that patient visits are often rushed, with as little as 8 minutes per patient. By converting their practices to a concierge model, doctors see fewer patients but spend more time with each one and still charge affordable fees, because they do not need several office staff members just to handle insurance paperwork.

Third, the concierge and DPC models allow doctors to use the additional time spent with each patient to focus on preventive health care rather than the treatment of existing disorders. Some concierge practices are using terms such as proactive or intensive health care to describe the personalized wellness programs that they offer their patients. MDVIP, a network of concierge practitioners that offers services compatible with most insurance plans, defines its approach is "proactive, not reactive" throughout its website, and uses the slogan "Long Live Healthy" to summarize its emphasis on preventive medicine and wellness education. It even describes its patients' relationships with their physicians as "one-on-one coaching" rather than "health care."

KEY TERMS

Direct primary care (DPC)—Healthcare delivery in which primary care is offered by the physician directly to the consumer without the involvement of an insurance company. DPC is sometimes used as a synonym for concierge medicine though many writers prefer to distinguish between the two models.

Medical tourism—The practice of seeking health care (most often elective surgical procedures) outside one's own country. It should not be confused with travel medicine, which is a medical specialty that deals with the prevention of disease and the treatment of medical emergencies in international travelers.

Primary care—Medical care offered by a physician, physician assistant, nurse practitioner, or other healthcare provider who is the patient's first contact with the healthcare system before the patient is referred to a specialist elsewhere in the system.

Retainer—A fee paid in advance to a doctor, lawyer, or other professional to secure services when needed.

Secondary care—Health care provided by specialist physicians and other healthcare providers (physical therapists, respiratory therapists, etc.) who do not usually have the initial contact with patients. Secondary care also includes acute care provided in hospital emergency departments.

Preparation

Preparation on patients' part may range from deciding to stay with their present primary-care physician if the doctor converts the practice to a concierge or direct-pay model or seek another healthcare provider, to making decisions about maintaining one's present health insurance coverage. One trend in concierge and DPC practices is to combine the direct-pay model with low-cost insurance for catastrophic expenses. Some writers refer to this combination as a hybrid model of concierge medicine. For example, Qliance began a pilot program with Cigna in which families could purchase inexpensive concierge care from Qliance and supplement it with lower-priced insurance coverage for unexpected emergencies. Employers in the Seattle area who use Qliance to provide their employees with basic primary care can also offer these employees high-deductible insurance plans needed to cover emergency hospitalization or visits to specialists.

Given the option of a hybrid model of direct-pay health care combined with insurance coverage, individual patients can choose to explore different concierge or DPC practices in their local area and decide which model of care is best for them. Such a decision will be highly personal, depending as it does on the individual patient's age, number of chronic health conditions, education and income level, family members' healthcare needs and concerns, geographic location and ease of travel, the length of time they have known their present primary-care physician, and other factors.

Risks

One potential risk involved in concierge medicine is that some patients either cannot afford even a modest retainer or choose not to participate in a concierge model and so may have to find another primary-care physician if their present doctor switches to a concierge practice. Some doctors think that the concierge model leads to some physicians having to add more patients to an

WWW.BOOKBAZ.IR

already heavy patient load when others in their area form concierge practices. However, many physicians with concierge practices are able to see some patients—including uninsured or even homeless patients—for very low fees because of their low office overhead.

Another risk for physicians and patients alike is inadequate thought and preparation preceding a physician's converting a practice to a concierge or direct-pay model. The AAPP has a section of its website containing advice to primary-care doctors on issues to consider before moving to a concierge practice model. These considerations include making sure that the new practice model will comply with all legal requirements; networking with other private-care physicians in the area; creating appropriate marketing materials; explaining the new practice model to insurers; and notifying office staff and patients in a responsible manner.

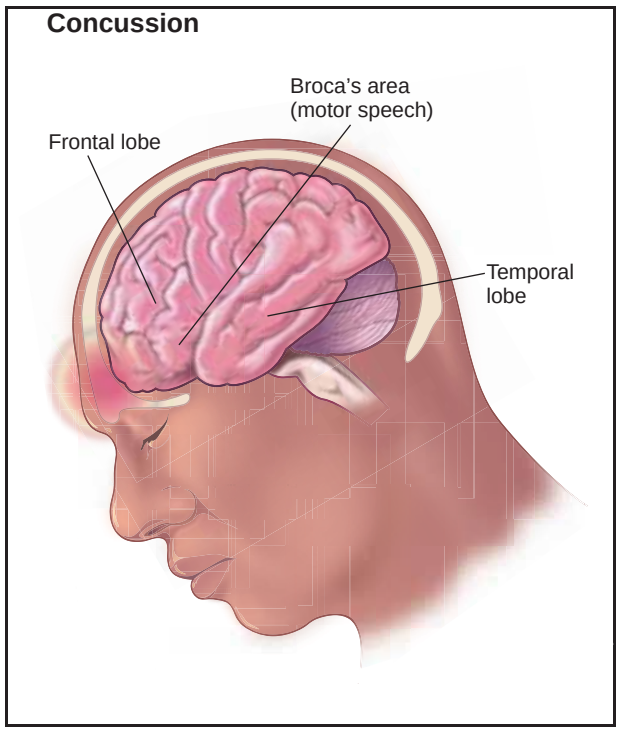
Concussion

Definition

A concussion is a trauma-induced change in mental status and may be associated with confusion and **amnesia**; it may or may not entail a brief loss of consciousness. Such injuries often follow a blow to the head or a very rapid acceleration of the head. Concussion is also called **traumatic brain injury**.



An illustration of the head and brain, depicting the impact of a concussion on the parts of the brain. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

A concussion occurs when the head hits or is hit by an object or when the brain is jarred against the skull, with sufficient force to cause temporary loss of function in the higher centers of the brain. The injured person may remain conscious or lose consciousness briefly and is disoriented for some minutes after the blow.

While concussion usually resolves on its own without lasting effect, it can set the stage for a much more serious condition. Second impact syndrome (SIS) occurs when a person with a concussion, even a very mild one, suffers a second blow (minutes, hours, days, or weeks) before fully recovering from the first. The mildest form of concussion can lead to SIS, which is why the condition is so serious. In fact, the brain swelling and increased intracranial pressure that can result is potentially fatal. For those who are not killed, severe disability often results. Most SIS cases occur in young people. For this reason, guidelines have been established to prevent SIS from happening. In fact, in the National Football League, athletes are not allowed to return to the game until their concussion symptoms have subsided.

Demographics

A concussion is a particular type of traumatic brain injury (TBI). According to the Centers for Disease Control and Prevention (CDC), a TBI is caused by a blow or jolt to the head or a penetrating **head injury** that disrupts the normal function of the brain. Clearly, not all blows or jolts to the head result in a TBI. TBI injuries can range from mild, which means a brief change in mental status or consciousness, to severe, which involves an extended period of unconsciousness or amnesia after the injury. The CDC states that at least 1.7 million TBIs occur annually in the United States either as an isolated injury or in association with other injuries. The majority (about 75%) of TBIs are concussions or other forms of mild TBI. Further, according to 2013 statistics from the CDC, TBI is a contributing factor in 30.5% of all injury-related deaths in the United States. For adults, those 75 years old and older have the highest rate of TBI-related hospitalization and death.

Costs to society

According to the CDC, in 2010, the direct medical costs and indirect costs due to lost work productivity from TBI totaled about $76.5 billion in the United States.

Causes and symptoms

Brain injuries cause more deaths than any other type of **sports injuries**. A common brain injury is the concussion. Concussions often follow a blow to the head or a very rapid acceleration of the head.

Causes

Playing contact sports is a risk factor for experiencing one or more concussions. According to the CDC, approximately 300,000 people sustain mild to moderate sports-related brain injuries each year. However, sports-related concussions are widely thought to be under reported because athletes do not want to be medically disqualified from continuing to play their sport. Most sports-related brain injuries occur in young men between the ages of 16 and 25 years.

The risk of concussion from football is extremely high, especially at the high school level. Studies show that approximately one in five players suffer concussion or more serious brain injury during their brief high-school careers. The rate at the collegiate level is approximately one in 20. Rates for hockey players are not known exactly but are believed to be similar.

WWW.BOOKBAZ.IR

Concussion and lasting brain damage is an especially significant risk for boxers, since the goal of the sport is, in fact, to deliver a concussion to the opponent. For this reason, the American Academy of Neurology has called for a ban on boxing. Repeated concussions over months or years can cause cumulative head injury. The cumulative brain injuries suffered by most boxers can lead to permanent brain damage. Multiple blows to the head can cause punch-drunk syndrome or **dementia** pugilistica, as experienced by former American boxer Muhammad Ali (1942–, born Cassius Marcellus Clay Jr.), whose Parkinson's syndrome (or parkinsonism) is a result of blows he endured in the boxing ring.

Falls account for the greatest number of concussions in children from the ages of birth to four years and in people over age 65. Individuals over the age of 75 years have the greatest rate of hospitalization and death from concussions.

Motor vehicle accident are most likely to cause concussions that result in death. The death rate from motor vehicle concussions is highest in males from the ages of 20 to 24 years. In motor vehicle accidents, concussion can occur without an actual blow to the head. Instead, concussion occurs because the skull suddenly decelerates or stops, which causes the brain to be jarred against the skull.

Symptoms

Symptoms of concussion include:

- headache
- disorientation as to time, date, or place
- confusion
- dizziness
- vacant stare or confused expression
- incoherent or incomprehensible speech
- weakness or lack of coordination
- amnesia for the events immediately preceding the blow
- nausea or vomiting
- double vision
- ringing in the ears

These symptoms may last from several minutes to several hours. More severe or longer-lasting symptoms may indicate more severe brain injury. The person with a concussion may or may not lose consciousness from the blow. More prolonged unconsciousness indicates more severe brain injury.

The severity of concussion is graded on a three-point scale, used as a basis for treatment decisions. These grades are:

- Grade 1: no loss of consciousness, transient confusion, and other symptoms that resolve within 15 minutes
- Grade 2: no loss of consciousness, transient confusion, and other symptoms that require more than 15 minutes to resolve
- Grade 3: loss of consciousness for any period

Days or weeks after the accident, the person may show symptoms of a condition called **post-concussion syndrome**. Signs of post-concussion syndrome are:

- headache
- poor attention and concentration
- memory difficulties
- anxiety
- depression
- sleep disturbances
- light and noise intolerance

Diagnosis

A medical professional will complete a comprehensive review of the injury. Thereafter, a neurological examination is performed that covers the following:

- memory and concentration
- vision
- hearing
- strength and sensation
- balance
- coordination
- reflexes

Examination

It is very important for those attending a person with concussion to pay close attention to the person's symptoms and progression immediately after the accident. The duration of unconsciousness and degree of confusion are important indicators of the severity of the injury and help guide the diagnostic process and treatment decisions.

A doctor, nurse, or emergency medical technician may conduct an immediate assessment based on the severity of the symptoms; a neurologic examination of the pupils, coordination, and sensation; and brief tests of orientation, memory, and concentration. Those with very mild concussions may not need to be hospitalized or have expensive diagnostic tests.

Tests

Questionable or more severe cases may require computed tomography (CT) scans or **magnetic**

resonance imaging (MRI) scans to look for brain injury. More extensive neuropsychologic testing may be done, especially on athletes who are at risk for repeat concussions.

Treatment

The symptoms of concussion usually clear quickly and without lasting effect, if no further injury is sustained during the healing process. Guidelines for returning to sports activities are based on the severity of the concussion.

A grade 1 concussion can usually be treated with rest and continued observation alone. The person may return to sports activities that same day but only after examination by a trained professional and after all symptoms have completely resolved. If individuals sustain a second concussion of any severity that same day, they should not be allowed to continue contact sports until they have been symptom-free, during both rest and activity, for one week.

Persons with a grade 2 concussion must discontinue sports activity for the day, should be evaluated by a trained professional, and should be observed closely throughout the day to make sure that all symptoms have completely cleared. Worsening of symptoms or continuation of any symptoms beyond one week indicates the need for a CT or MRI scan. Return to contact sports should only occur after one week with no symptoms, both at rest and during activity, and following examination by a physician. Following a second grade 2 concussion, individuals should remain symptom-free for two weeks before resuming contact sports.

Individuals with a grade 3 concussion (involving any loss of consciousness, no matter how brief) should be examined by a medical professional either on the scene or in an emergency room. More severe symptoms may warrant a CT or MRI scan, along with a thorough neurological and **physical examination**. These individuals should be hospitalized if any abnormalities are found or if confusion persists. Prolonged unconsciousness and worsening symptoms require urgent neurosurgical evaluation or transfer to a **trauma** center. Following discharge from professional care, these patients are closely monitored for neurological symptoms, which may arise or worsen. If headaches or other symptoms worsen or last longer than one week, a CT or MRI scan should be performed. Contact sports must be avoided for one week following unconsciousness of only seconds and for two weeks for unconsciousness of a minute or more.

For those who have sustained a concussion of any severity, it is critically important that they avoid the possibility of another blow to the head until well after all symptoms have cleared to prevent second-impact syndrome. The previous guidelines were designed to minimize the risk of this syndrome. Individuals receiving a second grade 3 concussion should avoid contact sports for at least a month after all symptoms have cleared and then only with the approval of a physician. If signs of brain swelling or bleeding are seen on a CT or MRI scan, these individuals should not return to the sport for the rest of the season or the rest of their lives.

Prognosis

About 90% of concussions leave no lasting neurological problems. Nonetheless, symptoms of postconcussion syndrome may last for weeks or even months.

Studies of concussion in contact sports have shown that the risk of sustaining a second concussion is even greater than it was for the first if the person continues to engage in the sport.

Prevention

Many cases of concussion can be prevented by using appropriate protective equipment, such as seat belts and air bags in automobiles and helmets in all contact sports. Helmets should also be worn when bicycling, skiing, skateboarding, horseback riding, and engaging in other activities where the brain needs protection from impact. Soccer players should avoid heading the ball when it is kicked at high velocity from close range. Playground equipment should be underlaid with soft material, either sand or special matting.

Risks

After a concussion, individuals risk complications if they return to sporting activities or other physical endeavors before their brain has healed. Athletes risk developing postconcussion syndrome, which includes such likely symptoms as **dizziness**, headaches, irritability, and difficulty with skills that require thinking and learning. Other symptoms include nausea and/or **vomiting**, blurry or double vision, sensitivity to sounds or visible light, memory problems, troubles sleeping, and numbness or tingling. At a young age, repeat concussions can add to these problems and make them even worst later in life.

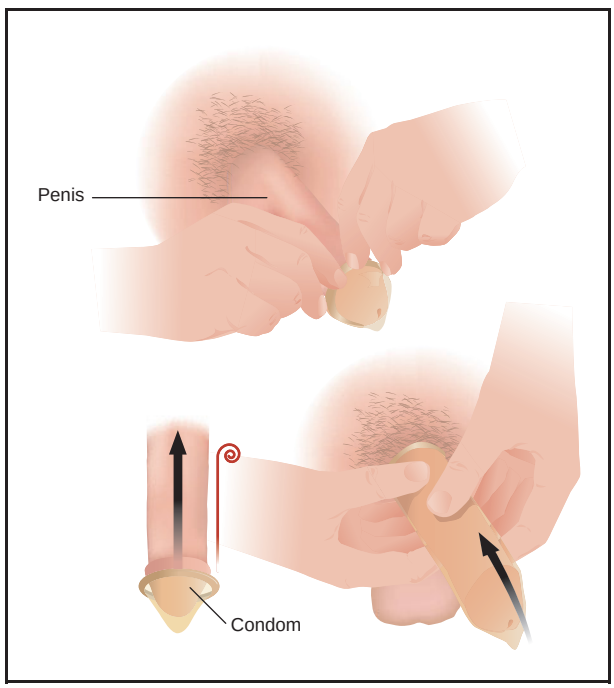
Condoms

Definition

Condoms are a barrier method of **contraception** intended to block the entry of semen from the male into the cervix of the female uterus, thus preventing fertilization of the female ovum. Most condoms are male-controlled contraceptive devices that consist of a thin flexible sheath placed over the erect male penis prior to intercourse. There are also female condoms, first introduced in 1984, that consist of a pouch with flexible rings at each end.



A condom is most effective when it is placed on the penis correctly without trapping air between the penis and the condom. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

The derivation of the term *condom* is unknown. There was an urban legend for many years that the name was derived from either a court physician named Dr. Condom or the Earl of Condom, supposedly a noble at the court of King Charles II of England (1630–1685). Charles was known as the "Merry Monarch" and his court was famous for its irresponsible pleasure-seeking; however, there are no records of anyone named Condom in the court circle, and condoms were in use in England for over a century before Charles became king in 1660. Most historians of medicine now state that the origin of the word *condom* cannot be traced.

Purpose

Both male and female condoms are used to prevent **pregnancy** and to protect against such sexually transmitted diseases (STDs) as human **immunodeficiency** virus (HIV), **gonorrhea**, chlamydia, and **syphilis**. To accomplish these goals, however, a condom must be applied and removed correctly. The Centers for Disease Control and Prevention (CDC) states, "To achieve the maximum protective effect, condoms must be used both consistently and correctly. Inconsistent use can lead to acquisition of a sexually transmitted disease (STD) because transmission can occur with a single act of intercourse with an infected partner. Similarly, if condoms are not used correctly, the protective effect may be diminished even when they are used consistently."

In addition to standard condoms used for contraception and disease **prophylaxis**, there are also specialized condoms used to collect male semen for artificial insemination or sperm analysis as part of an **infertility** workup. Collection condoms are usually made of silicone or polyurethane rather than latex, as latex is harmful to sperm and may yield inaccurate results when the number and viability of the sperm are measured.

Demographics

Condoms have been the most widely used method of contraception and disease prevention worldwide since they were first mass manufactured in the late nineteenth century. After birth control pills were introduced in 1960, condoms became the second most common method of birth control in the developed countries. In Japan, however, 80% of married couples still prefer condoms to other methods of birth control, compared to 28% of couples in the United States and Canada. In Africa, only 8% of couples use condoms as a method of contraception.

Although exact statistics of the number of condoms manufactured each year worldwide are difficult to obtain, it is safe to assume that billions are produced, as the number purchased by the government of India alone for distribution in family planning clinics is 2 billion per year.

Description

Both male and female condoms collect the male semen at ejaculation, acting as a barrier to fertilization. Condoms serve as barriers to the exchange of bodily fluids and are subsequently an important tool in the prevention of STDs.

Male condoms

Male condoms are thin sheaths of latex (rubber), polyurethane (plastic), or animal tissue that are rolled onto an erect penis immediately prior to intercourse. They are commonly called "safes," "rubbers," or "prophylactics," from their use in preventing disease. In England they are sometimes called "French letters."

Because many men and women are allergic to latex, the Food and Drug Administration (FDA) approved the use of Vytex for condoms sold in the United States in May 2009. Vytex is a form of latex that has been treated to remove 90% of the proteins that cause allergic reactions. A completely allergen-free condom made of polyisoprene, a synthetic latex, is also available. Polyisoprene is more expensive than standard latex but has the advantages of being as flexible and soft as latex without triggering allergic reactions.

Most condoms made of animal tissue as of 2014 are made from sheep intestines and are labeled as lambskin. They provide more sensation than latex and are also less likely to trigger allergic reactions. They are also significantly more expensive than latex condoms and offer less protection against STDs. The reason for this difference is that sheep intestine is a porous material whose pores are large enough to permit the HIV virus and other infectious organisms to pass through even though the pores are small enough to block sperm.

Male condoms may be purchased lubricated, ribbed, or studded on the outside. Studded condoms should not be used for anal intercourse, however, because they can irritate the tissues lining the rectum and increase the risk of HIV transmission. To be effective, condoms must be removed carefully so as not to "spill" the contents into the vaginal canal. Condoms that leak or break do not provide complete protection against pregnancy or disease, although they are more effective than completely unprotected intercourse.

WWW.BOOKBAZ.IR

Female condoms

Female condoms are made of polyurethane and are inserted into the vaginal canal before sexual relations. The open end covers the outside of the vagina, and the closed ring fits over the cervix (opening into the uterus). Newer female condoms are made of nitrile, a synthetic rubber that is also used to make disposable surgical gloves. Nitrile is as flexible as latex but is more resistant to puncture.

Origins

Male condoms made from animal tissue and linen have been in use for centuries. In Japan and China, upper-class men used condoms made from tortoise shell or animal horn. The first documented use of condoms in Europe dates from 1564, in a treatise on preventing syphilis. Syphilis, which first entered Europe in the 1490s, was an extremely virulent disease at that time and could cause death within a few months. The 1564 treatise described the use of linen sheaths soaked in some kind of chemical solution and dried before wearing. Condoms made from pig bladders or intestines were also used during the Renaissance. These devices were initially used in Europe to prevent STDs; the first reference to their use as contraceptives was published in 1605.

Latex condoms were introduced in the late 1800s and gained immediate popularity because they were inexpensive and effective. The German army was the first to recommend condoms to soldiers, beginning in the late nineteenth century. Although condoms were the first effective method of contraception that the poor could afford, a common complaint made then as now by many consumers is that condoms reduce penis sensitivity and impair satisfaction. In addition, both men and women may develop **allergies** to latex. Consumer interest in female condoms was relatively slight when it was first introduced; however, the fact that the female condom can be used by women whose partners refuse to use a male condom has increased its popularity in a number of countries.

Benefits

An important fact to keep in mind when reading statistics about condom effectiveness is the distinction between "perfect" or "method effectiveness" use rates and "actual" or "typical" use rates. Perfect or method effectiveness rates include only consumers who use condoms properly and consistently. Typical or actual use rates include all persons who use condoms, including those who use them incorrectly or do not use them during every act of intercourse. Thus, while perfect use of condoms results in a pregnancy rate of 2% per year, typical users have a pregnancy rate of 10% to 18% per year.

With regard to disease transmission, in 2000 the National Institutes of Health (NIH) reported that correct and consistent use of latex condoms reduces the risk of HIV/AIDS transmission by approximately 85% relative to a person's risk when unprotected. In 2007 the World Health Organization (WHO) reported a similar risk reduction rate of 80% to 95%. The CDC states that "Latex condoms, when used consistently and correctly, are highly effective in preventing the sexual transmission of HIV, the virus that causes **AIDS**. In addition, consistent and correct use of latex condoms reduces the risk of other sexually transmitted diseases (STDs), including diseases transmitted by genital secretions, and to a lesser degree, genital ulcer diseases."

With regard to contraception, male condoms have an effectiveness rate of about 90% for preventing pregnancy when used correctly and consistently, but this rate can be increased to about 98% if used with a spermicide that is applied separately. (Several types of spermicides are available; they can be purchased in the form of contraceptive creams and jellies, foams, or films.) Benefits associated with this type of contraceptive device include easy availability (no prescription is required), convenience of use, and absence of serious side effects. The primary disadvantage is that sexual activity must be interrupted in order to put on the male condom.

Female condoms, when used correctly and at every instance of intercourse, were shown to prevent pregnancy in over 95% of women surveyed over the course of six months. When used inconsistently, the female condom was shown to have a failure rate of 21% in the same study. One benefit of the female condom is that it may be inserted immediately before sexual intercourse or up to eight hours prior, so that sexual activity does not need to be interrupted for its insertion. One study performed by a manufacturer of the female condom indicated that 50–75% of couples in numerous countries found the barrier acceptable for use.

Precautions

Before purchasing a condom, the user should check the expiration date. Prior to use, examine the condom for holes. If a lubricant is going to be used with a latex condom, it should be water-soluble because petroleum jellies, such as Vaseline, and other oil-based lubricants can weaken latex. It is also

KEY TERMS

Carcinogen—Any substance or form of radiation that increases the risk of cancer or stimulates the growth of an existing cancer.

Contraception—The use of a device, sexual practice, or chemical intended to prevent conception; birth control.

Ejaculate—To expel semen.

Nonoxynol-9—The chemical name of the organic compound most commonly used in contraceptive creams, foams, and jellies. It was also used in the manufacture of spermicide-treated condoms until 2005, but the use of such condoms is now discouraged.

Perfect use—A measurement of the effectiveness of a contraceptive based only on those who use the method correctly and use it every time they have intercourse. It is also called the method effectiveness rate.

Prophylactic—A drug, medical device, or technique intended to prevent (rather than treat) disease. Condoms are sometimes called prophylactics.

Semen—The thick whitish liquid released from the penis during sexual intercourse. It contains sperm and other secretions.

Sperm or spermatozoa—The part of the semen that is generative—can cause fertilization of the female ovum.

Spermicide—An agent that is destructive to sperm.

Typical use—A measurement of the effectiveness of a contraceptive that counts all users, including those who use the method incorrectly or only occasionally.

Vagina—The genital canal in the female, leading from the vulva to the uterus.

important to note that condoms made from animal tissue or plastic are not recommended as a protection against STDs.

Spermicide-treated condoms are no longer recommended because the spermicide used in them, a chemical called nonoxynol-9, was reported in 2003 to actually increase the risk of transmitting HIV because it causes tiny tears or breaks in the tissues lining the vagina or rectum. In addition, spermicide-treated condoms increase the risk of urinary tract infections in the female partner. After 2005, several major manufacturers of condoms stopped producing condoms treated with spermicide.

Preparation

A person intending to use a condom should avoid heavy drinking or drug use prior to having sex, because intoxication or a drug "high" can impair judgment and increase the risk of using the condom incorrectly.

A male condom should be removed carefully from its foil wrapper and placed on the tip of the erect penis. Leaving some space at the tip of the condom to collect the semen, the user then unrolls the condom downward toward the base of the penis.

To use a female condom, the woman inserts a flexible ring at the closed end of the sheath deep into the vagina; this ring holds the device in place. The flexible ring at the open end of the sheath remains outside the opening to the vagina and serves to guide the man's penis into the vagina.

Aftercare

To remove a male condom after use, the user should withdraw carefully, holding the condom around the base of the penis. To remove a female condom, the user should twist the outer ring shut and gently withdraw the condom from the vagina. Because most condoms are not biodegradable, they should not be flushed down toilets. Instead, they should be wrapped in toilet paper or a paper towel and discarded in a waste container.

Risks

In addition to the risks of pregnancy or disease transmission from incorrect or inconsistent use, condoms have been associated with risks from substances used in their manufacture. Nitrosamines, which are chemicals identified as carcinogenic in humans, are used by some manufacturers of latex condoms to increase the flexibility of the latex. One group of German researchers reported in 2005 that nitrosamines can migrate from rubber products into human sweat or tissue fluid.

Another risk of condom use is partner violence in some cultures and ethnic groups. Women in Africa and in some Latino subcultures in developed countries have reported threats of violence from their partners if they ask the men to use condoms as a form of contraception. In addition, there is a high correlation of alcohol abuse, condom non-use, and sexual assaults on women.

WWW.BOOKBAZ.IR

Research and general acceptance

Condoms are widely accepted as an effective method of contraception and disease prophylaxis. Research is ongoing, however, into improving the effective use of condoms among drug users and other high-risk populations, and into newer types of condoms. These newer types include:

- Rape-aXe. Rape-aXe is a female condom that has been produced since 2006. It consists of a latex sheath containing sharp barbs. The woman inserts the device like a tampon. If a male attacker attempts vaginal penetration, the device attaches itself to his penis and requires surgical removal, thus identifying the rapist.
- Spray-on condoms. As of 2010, several companies are working on developing a latex formula that could be sprayed on the penis and allowed to dry. This product was not widely marketed as of 2014.
- A so-called invisible condom. Developed by a university in Quebec, the invisible condom is a gel that hardens after insertion into the vagina or rectum, and then liquefies after several hours. It is still in the clinical trials phase.
- Condoms containing lubricants intended to help the male partner maintain his erection, thus reducing the risk of condom slippage. These condoms are also still in clinical trials.

Conduct disorder

Definition

Conduct disorder (CD) is a behavioral and emotional disorder of childhood and adolescence. Children with conduct disorder act inappropriately, infringe on the rights of others, and violate the behavioral expectations of others.

Description

CD is present in approximately 9% of boys and 2–9% of girls under the age of 18. Children with conduct disorder act out aggressively and express anger inappropriately. They engage in a variety of antisocial and destructive acts, including violence toward people and animals, destruction of property, lying, stealing, truancy, and running away from home. They often begin using and abusing drugs and alcohol, and having sex at an early age. Irritability, temper tantrums, and low self-esteem are common personality traits of children with CD.

Causes and symptoms

There are two sub-types of CD, one beginning in childhood and the other in adolescence. There is no known cause. Researchers and physicians suggest that this disease may be caused by the following:

- poor parent-child relationships
- dysfunctional families
- drug abuse
- physical abuse
- poor relationships with other children
- cognitive problems leading to school failures
- brain damage
- biological defects

Difficulty in school is an early sign of potential conduct disorder problems. While the patient's IQ tends to be in the normal range, they can have trouble with verbal and abstract reasoning skills and may lag behind their classmates, and consequently, feel as if they don't "fit in." The frustration and loss of self-esteem resulting from this academic and social inadequacy can trigger the development of CD.

A dysfunctional home environment can be another major contributor to CD. An emotionally, physically, or sexually abusive home environment, a family history of antisocial personality disorder, or parental substance **abuse** can damage a child's perceptions of himself and put him on a path toward negative behavior. Other less obvious environmental factors can also play a part in the development of conduct disorder. Long-term studies have shown that maternal **smoking** during **pregnancy** may be linked to the development of CD in boys. Animal and human studies point out that nicotine can have undesirable effects on babies. These include altered structure and function of their nervous systems, learning deficits, and behavioral problems. In a study of 177 boys ages 7 to 12 years, those with mothers who smoked over one-half a package of cigarettes daily while pregnant were more apt to have a CD than those with mothers who did not smoke.

Other conditions that may cause or co-exist with CD include **head injury**, substance abuse disorder, major depressive disorder, and **attention deficit hyperactivity disorder (ADHD)**. Thirty to 50 percent of children diagnosed with **ADHD**, a disorder characterized by a persistent pattern of inattention and/or hyperactivity, also have CD.

CD is defined as a repetitive behavioral pattern of violating the rights of others or societal norms. Three of the following criteria, or symptoms, are required over the previous 12 months for a diagnosis of CD (one of the three must have occurred in the past 6 months):

- bullies, threatens, or intimidates others
- picks fights
- has used a dangerous weapon
- has been physically cruel to people
- has been physically cruel to animals
- has stolen while confronting a victim (for example, mugging or extortion)
- has forced someone into sexual activity
- has deliberately set a fire with the intention of causing damage
- has deliberately destroyed property of others
- has broken into someone else's house or car
- frequently lies to get something or to avoid obligations
- has stolen without confronting a victim or breaking and entering (e.g., shoplifting or forgery)
- stays out at night; breaks curfew (beginning before 13 years of age)
- has run away from home overnight at least twice (or once for a lengthy period)
- is often truant from school (beginning before 13 years of age)

Diagnosis

CD is diagnosed and treated by a number of social workers, school counselors, psychiatrists, and psychologists. Genuine diagnosis may require psychiatric

WWW.BOOKBAZ.IR

expertise to rule out such conditions as **bipolar disorder** or ADHD. A comprehensive evaluation of the child should ideally include interviews with the child and parents, a full social and medical history, a cognitive evaluation, and a psychiatric exam. One or more clinical inventories or scales may be used to assess the child for conduct disorder—including the Youth Self-Report, the Overt Aggression Scale (OAS), Behavioral Assessment System for Children (BASC), Child Behavior Checklist (CBCL), and Diagnostic Interview Schedule for Children (DISC). The tests are verbal and/or written and are administered in both hospital and outpatient settings.

Treatment

Treating conduct disorder requires an approach that addresses both the child and his environment. Behavioral therapy and **psychotherapy** can help a child with CD to control his anger and develop new coping skills. Family **group therapy** may also be effective in some cases. Parents should be counseled on how to set appropriate limits with their child and be consistent and realistic when disciplining. If an abusive home life is at the root of the conduct problem, every effort should be made to move the child into a more supportive environment. Parent training programs are increasing in number.

For children with coexisting ADHD, substance abuse, depression, or **learning disorders**, treating these conditions first is preferred, and may result in a significant improvement to the CD condition. In all cases of CD, treatment should begin when symptoms first appear. Recent studies have shown Ritalin to be a useful drug for both ADHD and CD.

When aggressive behavior is severe, mood stabilizing medication, including lithium (Cibalith-S, Eskalith, Lithane, Lithobid, Lithonate, Lithotabs), carbamazepine (Tegretol, Atretol), and propranolol (Inderal), may be an appropriate option for treating the aggressive symptoms. However, placing the child into a structured setting or treatment program such as a psychiatric hospital may be just as beneficial for easing aggression as medication.

Prognosis

The prognosis for children with CD is not bright. Follow-up studies of conduct disordered children have shown a high incidence of antisocial personality disorder, affective illnesses, and chronic criminal behavior later in life. However, proper treatment of co-existing disorders, early identification and intervention, and long-term support may improve the outlook significantly.

KEY TERMS

ADHD—Attention deficit hyperactivity disorder; a disorder characterized by a persistent pattern of inattention and/or hyperactivity.

Major depressive disorder—A mood disorder characterized by profound feelings of sadness or despair.

Prevention

A supportive, nurturing, and structured home environment is believed to be the best defense against CD. Children with learning disabilities and/or difficulties in school should get immediate and appropriate academic assistance. Addressing these problems when they first appear helps to prevent the frustration and low self-esteem that may later lead to CD.

Congenital adrenal hyperplasia

Definition

Congenital adrenal hyperplasia (CAH) is a genetic disorder that affects the adrenal glands, a pair of walnut-sized organs located over the kidneys. It is characterized primarily by a deficiency in the steroid hormone group glucocorticoid (usually cortisol), and secondarily by deficient amounts of the steroid hormone group mineralocorticoid (usually

Adrenal cortical hyperplasia. The adrenal on the right is normal; the one on the left shows hyperplasia. *(© Biophoto Associates/Photo Researchers, Inc.)*

aldosterone). Because these two hormones are produced in lower-than-normal amounts, CAH is also secondarily characterized by an over-production of the steroid hormone group androgen (such as testosterone). Due to it being hereditarily caused, CAH is present at birth. CAH affects the sexual development of children.

Demographics

CAH is a genetic disorder that interferes with the normal growth and development, especially the sexual development. It affects male and female children equally. According to the National Institutes of Health, about one child in 10,000 to 18,000 children in the United States are born with congenital adrenal hyperplasia. It also affects adults, men and women equally, in all populations of the world. It is especially common in Yupik Eskimos, where the incidence is about one in 400.

Congenital adrenal hyperplasia is the most common adrenal gland disorder found in infants and children, occurring in one in 10,000 total births worldwide. It is also called adrenogenital syndrome.

Description

Congenital adrenal hyperplasia (CAH) is a form of adrenal insufficiency in which the enzyme that produces two important adrenal steroid hormones, cortisol and aldosterone, is deficient. Cortisol and aldosterone play roles in maintaining the body's health. Therefore, a low concentration of cortisol makes it difficult for a body to regulate blood pressure, maintain blood sugar levels, and energy levels. In addition, low levels of aldosterone produce lower **sodium** levels and higher potassium levels, which when not in balance can adversely effect muscle and nerve control.

Because cortisol and aldosterone production is impeded, the adrenal gland instead overproduces androgens (male steroid hormones). Consequently, females with CAH are generally born with genitals that appear more male than female, such as an enlarged clitoris (which is called ambiguous external genitalia). They may also develop other male characteristics. However, females will possess normal internal reproductive tract structures (such as ovaries, fallopian tubes, and uterus). Males usually have normal genitals at birth but may experience premature sexual development; however, in a small percentage of cases such male infants have an enlarged penis. CAH causes abnormal growth for both sexes; with patients being tall as children but short as adults.

In its most severe form, called salt-wasting CAH, a life-threatening adrenal crisis can occur if the disorder is untreated. This form, which occurs in newborns and very young children, is also called classic congenital adrenal hyperplasia. The adrenal crisis can cause **dehydration**, **shock**, and death within 14 days of birth. There is also a mild form of CAH, which occurs later in childhood or young adult life. This form of CAH, called non-classic congenital adrenal hyperplasia, causes patients to have a partial enzyme deficiency.

Risk factors

Because it is an hereditary disease, a child or fetus is at increased risk if both parent have CAH or if both parents are carriers of the disease. Some ethnic groups have a higher risk for getting congenital adrenal hyperplasia than others. Ashkenazi Jews, who have descended from along the Rhine River in Germany, are most likely to contract CAH. Others at high risk include Eskimos, Hispanics, Italians, and Yugoslavs (a small group of southern Slavic people originally found in the former Yugoslavia).

Causes and symptoms

CAH is an inherited disorder that occurs when one of many different enzymes, which are used by the adrenal glands to produce cortisol, is not produced in sufficient quantities. The most common enzyme associated with the disorder is 21-hydroxylase. Consequently, CAH is also sometimes called 21-hydroxylase deficiency. (Two other enzymes associated with CAH are 1-beta-hydroxylase and 17-alpha-hydroxylase.) Because varied amounts of 21-hydroxylase are produced within the human body, the degree that CAH affects people is different. Some people have severe cases of CAH, while others have only mild cases.

WWW.BOOKBAZ.IR

CAH is a recessive disease, which means that a child must inherit one copy of the defective gene from each parent who is a carrier; when two carriers have children, each **pregnancy** carries a 25% risk of producing an affected child.

The symptoms inherent within this condition are due to the fetus manufacturing lower-than-normal levels of cortisol and being exposed to abnormally high levels of male sex hormones (androgens). In females, CAH produces an enlarged clitoris at birth and masculinization of features as the child grows, such as deepening tone of voice, facial hair, excess facial and armpit hair, and failure to menstruate or abnormal periods at **puberty**. Females with severe CAH may be mistaken for males at birth. In males, the genitals are usually normal at birth, but the child becomes muscular, the penis enlarges while the testes remain small, pubic and armpit hair appears, and the voice deepens long before normal puberty, sometimes as early as two to three years of age.

In the severe salt-wasting form of CAH, newborns may develop symptoms shortly after birth, including **vomiting**, dehydration, weight loss (and inability to regain birth weight), electrolyte (a compound such as sodium or **calcium** that separates to form ions when dissolved in water) changes, and cardiac arrhythmia.

In the mild form of CAH, which first occurs in late childhood or early adulthood, symptoms include early and excessive development of body hair, **fatigue**, high blood **cholesterol**, low blood pressure, low bone density, nausea, **obesity**, reduced ability to cope with infections, and severe **acne**. Even though the older child grows rapidly, once adulthood is reached, the eventual height of the person is usually shorter than normal. In addition, most males and females with CAH are infertile as adults. Women also have unusually irregular menstrual cycles. However, sometimes symptoms are not present.

Diagnosis

CAH is diagnosed by a careful examination of the genitals and blood and urine tests that measure the hormones produced by the adrenal gland. Abnormal levels of cortisol, aldosterone, and androgen will confirm the diagnosis. A number of states in the United States perform a hormonal test (a heel prick blood test) for CAH and other inherited diseases within a few days of birth. In questionable cases, **genetic testing** can provide a definitive diagnosis. For some forms of CAH, prenatal diagnosis is possible through chronic villus sampling in the first trimester and by measuring certain hormones in the amniotic fluid (within the womb) during the second trimester; what is called **amniocentesis**. Such tests are performed when parents (or other family members) are known carriers or have the disease, or older siblings of the parents have CAH.

Treatment

The goal of treatment for CAH is to return the androgen levels to normal. This is usually accomplished through drug therapy, although surgery is an alternative. Lifelong treatment is required.

Drug therapy consists of one of a group of cortisol-like steroid medications called glucocorticoids. Oral hydrocortisone is prescribed for children, and prednisone or dexamethasone is prescribed for older patients. For patients with salt-wasting CAH, fludrocortisone, which acts like aldosterone (the missing hormone), is also prescribed. Infants and small children may also receive salt tablets, while older patients are told to eat salty foods. Medical therapy achieves hormonal balance most of the time, but CAH patients can have periods of fluctuating hormonal control that lead to increases in the dose of **steroids** prescribed. Side effects of steroids include stunted growth. Steroid therapy should not be suddenly stopped, since adrenal insufficiency results.

Patients with CAH should see a pediatric endocrinologist frequently. The endocrinologist will assess height, weight, and blood pressure, and order an annual x ray of the wrist (to assess bone age [bone mass]), as well as assess blood hormone levels. CAH patients with the milder form of the disorder are usually effectively treated with hydrocortisone or prednisone, if they need medical treatment at all.

Females with CAH who have masculine external genitalia require surgery to reconstruct the clitoris and/or vagina. This is usually performed between the ages of one and six months.

An experimental type of drug therapy—a three-drug combination, with an androgen blocking agent (flutamide), an aromatase inhibitor (testolactone), and low dose hydrocortisone—is currently being studied by physicians at the National Institutes of Health. Preliminary results are encouraging, but it will be many years before the safety and effectiveness of this therapy is fully known.

Adrenalectomy, a surgical procedure to remove the adrenal glands, is a more radical treatment for CAH. It was widely used before the advent of steroids. Currently, it is recommended for CAH patients with little or no enzyme activity and can be accomplished by **laparoscopy**. This is a minimally invasive type of

KEY TERMS

Adrenal glands—The two endocrine glands located above the kidney that secrete hormones and epinephrine.

Aldosterone—A hormone secreted by the adrenal glands that is important for maintaining salt and water balance in the body.

Androgens—Steroid hormones that cause masculinization.

Congenital—Present at birth.

Cortisol—A steroid hormone secreted by the adrenal cortex that is important for maintenance of body fluids, electrolytes, and blood sugar levels.

Hormone—A chemical messenger produced by the endocrine glands or certain other cells. Hormones are usually carried in the blood stream and regulate some metabolic activities.

Steroids—Hormones, including aldosterone, cortisol, and androgens, derived from cholesterol that share a four-ring structure.

surgery done through one or more small 1 in. (2.5 cm) incisions and a laparoscope, an instrument with a fiber-optic light containing a tube with openings for surgical instruments. Adrenalectomy is followed by hormone therapy, but in lower doses than CAH patients not treated surgically receive.

Prenatal treatment is also possible to diagnose CAH in a fetus. If diagnosed within the fetus, the doctor can prescribe a cortisosteroid drug, such as dexamethasone, to the pregnant woman. The drug will enter the womb from the mother's placenta and help to bring the fetus' adrenal glands back to normal function. A stronger dose of dexamethasone is usually prescribed for female fetuses and a milder dose to males.

Prognosis

Although CAH can potentially cause death in those it affects, the disorder can be controlled and successfully treated in most patients as long as they remain on drug therapy. When drug therapy is successfully applied, CAH patients usually lead normal lives. People with CAH will usually be shorter in height than most people, and they often times have fertility problems throughout their adult lives. Women are more likely to experience various sexual problems later in life if they had corrective surgery on their genitals. People with CAH may need some counseling to deal with their problems, but in all likelihood should lead a healthy and long life with proper treatment and care by their physician.

Prevention

Prenatal therapy, in which a pregnant woman at risk for a second CAH child is given dexamethasone to decrease secretion of androgens by the adrenal glands of the female fetus, has been in use for over ten years. This therapy is started in the first trimester when fetal adrenal production of androgens begins, but before prenatal diagnosis is done that would provide definitive information about the sex of the fetus and its disease status. This means that a number of fetuses are exposed to unnecessary steroid treatment in order to prevent the development of male-like genitals in female fetuses with CAH. Several hundred children have undergone this treatment with no major adverse effects, but its long-term risks are unknown. Since there is very little data on the effectiveness and safety of prenatal therapy, it should only be offered to patients who clearly understand the risks and benefits and who are capable of complying with strict monitoring and follow-up throughout pregnancy and after the child is born.

Parents with a family history of CAH, including a child who has CAH, should seek **genetic counseling**. Genetic testing during pregnancy can provide information on the risk of having a child with CAH.

Congenital amputation

Definition

Congenital **amputation** is the absence of a fetal limb or fetal part at birth. This condition may be the result of the constriction of fibrous bands within the membrane that surrounds the developing fetus (amniotic band syndrome) or the exposure to substances known to cause **birth defects** (teratogenic agents). Other factors, including genetics, may also play a role.

Description

An estimated one in 2,000 babies are born with all or part of a limb missing, ranging from a missing part of a finger to the absence of both arms and both legs. Congenital amputation is the least common reason for amputation. However, there are occasional periods in history where the number of congenital amputations increased. For example, the thalidomide tragedy of the early 1960s occurred after pregnant mothers in western Europe were given a tranquilizer containing the drug. The result was a drastic increase in the number of babies born with deformed limbs. In this example, the birth defect usually presented itself as very small, deformed versions of normal limbs. More recently, birth defects as a result of radiation exposure near the site of the Chernobyl disaster in Russia have left numerous children with malformed or absent limbs.

Causes and symptoms

The exact cause of congenital amputations is unknown. However, according to the March of Dimes, most birth defects have one or more genetic factors and one or more environmental factors. It is also known that most birth defects occur in the first three months of **pregnancy**, when the organs of the fetus are forming. Within these crucial first weeks, frequently prior to when a woman is aware of the pregnancy, the developing fetus is most susceptible to substances that can cause birth defects (teratogens). Exposure to teratogens can cause congenital amputation. In other cases, tight amniotic bands may constrict the developing fetus, preventing a limb from forming properly if at all. It is estimated that this amniotic band syndrome occurs in between one in 12,000 and one in 15,000 live births.

An infant with congenital amputation may be missing an entire limb or just a portion of a limb. Congenital amputation resulting in the complete absence of a limb beyond a certain point (and leaving a stump) is called transverse deficiency or amelia. Longitudinal deficiencies occur when a specific part of a limb is missing; for example, when the fibula bone in the lower leg is missing, but the rest of the leg is intact. Phocomelia is the condition in which only a mid-portion of a limb is missing, as when the hands or feet are attached directly to the trunk.

Diagnosis

Many cases of congenital amputation are not diagnosed until the baby is born. **Ultrasound** examinations may reveal the absence of a limb in some developing fetuses, but routine ultrasounds may not pick up signs of more subtle defects. If a doctor suspects that the fetus is at risk for developing a limb deficiency (for example, if the mother has been exposed to radiation), a more detailed ultrasound examination may be performed.

Treatment

Successful treatment of a child with congenital amputation involves an entire medical team, including a pediatrician, an orthopedist, a psychiatrist or psychologist, a prosthetist (an expert in making **prosthetics**, or artificial limbs), a social worker, and

KEY TERMS

Amniotic band—An abnormal condition of fetal development in which fibrous bands of tissue develop out of the amniotic sac. The bands encircle and constrict parts of the baby's body, interfering with normal development and sometimes causing congenital amputation.

Prosthesis—An artificial replacement for a missing part of the body.

Teratogen—Any substance, agent, or process that interferes with normal prenatal development, causing the formation of one or more developmental abnormalities of the fetus.

occupational and physical therapists. The accepted method of treatment is to fit the child early with a functional prosthesis because this leads to normal development and less wasting away (atrophy) of the muscles of the limbs present. However, some parents and physicians believe that the child should be allowed to learn to play and perform tasks without a prosthesis, if possible. When the child is older, he or she can be involved in the decision of whether or not to be fitted for a prosthesis.

In the case of congenital amputation of the fingers, **plastic surgery** can sometimes be used to reconstruct the missing digits by transferring parts of the great and second toes to the hand. Some defects in the leg bones can be treated by removing the malformed bone, grafting bone from other parts of the child's body, and inserting a metal rod to strengthen the limb; this technique, however, is controversial.

There have been cases in which physicians have detected amniotic band constriction interfering with limb development fairly early in its course. In 1997, doctors at the Florida Institute for Fetal Diagnosis and Therapy reported two cases in which **minimally invasive surgery** freed constricting amniotic bands and preserved the affected limbs.

Alternatives

Prevention of birth defects begins with building the well-being of the mother before pregnancy. Prenatal care should be strong and educational so that the mother understands both her genetic risks and her environmental risks. Several disciplines in alternative therapy also recommend various supplements and **vitamins** that may reduce the chances of birth defects. If a surgical procedure is planned, naturopathic and homeopathic pre- and post-surgical therapies can speed recovery.

Prognosis

A congenital limb deficiency has a profound effect on the life of the child and parents. **Occupational therapy** can help the child learn to accomplish many tasks. In addition, some experts believe that early fitting of a prosthesis will enhance acceptance of the prosthesis by the child and parents.

Prevention

Studies have suggested that a multivitamin including **folic acid** may reduce birth defects, including congenital abnormalities. **Smoking**, drinking alcohol, and eating a poor diet while pregnant may increase the risk of congenital abnormalities. Daily, heavy exposure to chemicals may be dangerous while pregnant.

Congenital bladder anomalies

Definition

The two most common congenital bladder abnormalities are exstrophy and congenital diverticula. An exstrophic bladder is one that is open to the outside and turned inside-out, so that its inside is visible at birth, protruding from the lower abdomen. A diverticulum is an extension of a hollow organ, usually shaped like a pouch with a narrow opening.

Description

During fetal development, folds enclose tissues and organs and eventually fuse at the edges to form sealed compartments. Both in the front and the back, folds eventually become major body structures. In the back, the entire spinal column folds in like a pipe wrapped in a pillow. In the front, the entire lower urinary system is folded in.

- Exstrophy of the bladder represents a failure of this folding process to complete itself, so the organs form with more or less of their front side missing and open to the outside. At the same time, the front of the pelvic bone is widely separated. The abdominal wall is open, too. In fact, the defect often extends all the way to the penis in the male or splits the clitoris in the female.
- A congenital bladder diverticulum represents an area of weakness in the bladder wall through which extrudes some of the lining of the bladder. (A small balloon squeezed in a fist will create a diverticula-like effect between the fingers.) Bladder diverticula may be multiple, and they often occur at the ureterovesical junction—the entrance of the upper urinary system into the bladder. In this location, they may cause urine to reflux into the ureter and kidney, leading to infection and possible kidney damage.

Causes and symptoms

As with many **birth defects**, the causes are not well known. Lack of prenatal care and **nutrition** has been linked to many birth defects, however beyond the avoidance of known teratogens (anything that can cause a birth defect), there is little prevention possible. Exstrophy is rare, occurring in about one in 40,000 births. Diverticula are more common, but less serious.

If left untreated, the patient with bladder exstrophy will have no control over urination and is more likely to develop **bladder cancer**. Diverticula, particularly if it causes urine reflux, may lead to chronic infection and its subsequent consequences.

Diagnosis

A major consideration with congenital abnormalities is that they tend to be multiple. Further, each one is unique in its extent and severity. Exstrophy can involve the rectum and large bowel and coexist with hernias. The obvious bladder exstrophy seen at birth will prompt immediate action and a search for other anomalies.

Diverticula are not visible and will be detected only if they cause trouble. They are usually found in an examination for the cause of recurring urinary infections. X rays of the urinary system or a **cystoscopy** (examination with a telescope-like instrument) will identify them. Often, the two procedures are done together: a urologist will perform the cystoscopy, then a radiologist will instill a contrast agent into the bladder and take x rays.

Treatment

Surgery is necessary and can usually produce successful results. If possible, the surgery must be done within 48 hours of birth. Prior to surgery, the exposed organs must be protected and all related defects identified and managed. Delay in the surgery leads to the frequent need to divert the urine into the bowel because the partially repaired bladder cannot control the flow. After surgery, the likelihood of infection requires monitoring.

Alternatives

After surgery, ongoing precautions to reduce frequency of infection may need to be used. Cranberry juice has the ability to keep bacteria from adhering to the membranes and can help prevent infection whenever there is increased risk. There are botanical and homeopathic treatments available; however, consultation by a trained practitioner is recommended before treatment.

Prognosis

With immediate surgery, three-quarters of patients can be successfully repaired. They will have control of their urine and no long-term consequences. The rate of infection is greater for those with congenital bladder anomalies, since any abnormality in the urinary system predisposes it to invasion by bacteria.

Prevention

Birth defects often have no precisely identified cause, therefore, prevention is limited to general

KEY TERMS

Congenital—Present at birth.

Cystoscopy—Examination of the urinary bladder with a thin telescope-like instrument.

Exstrophy—Being turned inside out combined with being outside the body.

Diverticulum—A pouch extending from a hollow organ.

Radiologist—A physician who specializes in creating images of the internal organs of the body.

Teratogen—Any agent that can cause birth defects.

Ureter—The tube that transports urine from the kidney to the bladder.

Ureterovesical junction—The joining of the ureter to the bladder.

Urologist—A physician who specializes in diseases of the urinary system.

measures such as early and continuous prenatal care, appropriate nutrition, and a healthy lifestyle.

Congenital bladder diverticulum *see* **Congenital bladder anomalies**

Congenital brain defects

Definition

Congenital brain defects are a group of disorders involving deficiencies of brain development. People are born with such brain defects (damage); thus, they are called congenital, or existing at birth. (Those brain defects that result from **trauma** or other types of injuries are called acquired brain defects, or non-congenital brain defects.) Congenital brain detects develop during the growth and development of the fetus. They are caused by a variety of factors, such as genetic defects, infections, prenatal problems, and environmental toxins. The causal factors disrupt the development of the brains of these fetuses, which, for the most part, leads to physical and cognitive problems after birth. Many disorders can be grouped within congenital brain defects.

Demographics

Congenital brain defects can occur in any population of humans around the world. They primarily affect fetuses within the womb or, in some cases, infants who have just been born. They do not generally favor one particular race or gender, although some of the disorders within congenital brain defects may favor a particular race or gender.

Description

Brain development begins shortly after conception and continues throughout the growth of a fetus. A complex genetic program coordinates the formation, growth, and migration of billions of neurons, or nerve cells, and their development into discrete, interacting brain regions. Interruption of this program, especially early in development, can cause structural defects in the brain. In addition, normal brain formation requires proper development of the surrounding skull, and skull defects may lead to brain malformation. Congenital brain defects may be caused by inherited genetic defects, spontaneous mutations within the genes of the embryo, or effects on the embryo due to infection, trauma, drug use, or environmental factors from the mother.

Some of the disorders grouped within congenital brain defects are anencephaly, encephalocele, **spina bifida**, Dandy-Walker malformation, holoprosencephaly, lissencephaly, schizencephaly, schizencephaly, and megalencephaly.

Anencephaly

Early on in embryonic development, a flat strip of tissue along the back of the fetus rolls up to form a tube. This so-called "neural tube" develops into the spinal cord and, at one end, the brain. Closure of the tube is required for subsequent development of the tissue within. Anencephaly (literally "without brain"), results when the topmost portion of the tube fails to close, which results in the absence of most of the brain (primarily the cerebral hemispheres and cerebellum) and skull. Anencephaly is the most common severe malformation seen in stillborn births. According to the National Institutes of Health, it occurs in about one out of 10,000 births; however, the exact

WWW.BOOKBAZ.IR

figure is unknown because many pregnancies end up as miscarriages. It is about four times more common in females than males. Anencephaly is sometimes seen to run in families, and for parents who have conceived one anencephalic fetus, the risk of a second is as high as 5%. Fewer than half of babies with anencephaly are born alive, and survival beyond the first month is rare, with most babies dying within the first few days of being born.

Encephalocele

Encephalocele is a rare type of neural tube defect (NTD) that results in a sac-like protrusion (or projection) of part of the brain through a defect in the skull. It happens during **pregnancy** when the neural tube does not close completely. The most common site for encephalocele is along the front-to-back midline of the skull, usually at the rear, although frontal encephaloceles (in an area between the forehead and the nose) are more common among Asians. Pressure within the skull pushes out cranial tissue. The protective layer over the brain, the meninges, grows to cover the protrusion, as does skin in some cases. Defects in skull closure are thought to cause some cases of encephalocele, while defects in neural tube closure may cause others. Encephaloceles may be small and contain little or no brain tissue, or may be quite large and contain a significant fraction of the brain. The Centers for Diseases Control and Prevention states that in any given year about 375 babies are born in the United States with encephalocele; that is, about one in 10,000 births involve babies with encephalocele.

Spina Bifida

Failure of neural-tube closure below the level of the brain prevents full development of the surrounding vertebral bones and leads to spina bifida, or a divided spinal column. The medical community usually classifies three types of spina bifida. In spina bifida occulta, only a small separation in one or more vertebral bones of the spinal column occurs. This mild form of spina bifida usually involves few if any symptoms because the nerves within the spine are not adversely affected. Most children grow up without any problems. The only sign that may occur is a small lump or tiny tuft of hair near the spine. The second type, called meningocele, is a rare form of the condition, one in which the membranes around the spinal cord (the meninges) are pushed out through an opening in the vertebrae. Since the spinal cord develops normally, surgeons can remove the problematic membranes with little risk of further complications to the spine. In the third type, incomplete closure of the neural tube causes a protrusion of the spinal cord and meninges. This type is called myelomeningocele (also called open spina bifida or spina bifida cystica), and is the most severe form of spina bifida. In fact, when spina bifida is mentioned in common usage people are usually discussing myelomeningocele. Some cases of spina bifida are accompanied by another defect at the base of the brain, known as the Arnold-Chiari malformation or Chiari II malformation. For reasons that are unclear, part of the cerebellum is displaced downward into the spinal column. Symptoms may be present at birth or delayed until early childhood.

Dandy-Walker Malformation

The Dandy-Walker malformation (DWM) is marked by incomplete formation, or absence of, the central section of the cerebellum, and the growth of cysts within the lowest of the brain's ventricles (the fourth ventricle). The cerebellum helps to coordinate movement for humans, along with assisting in behavior and cognition (learning). The ventricles are fluid-filled cavities within the brain, through which cerebrospinal fluid (CSF) normally circulates. The cysts may block the exit of the fluid, causing **hydrocephalus**. Symptoms may be present at birth or delayed until early childhood. DWM usually results in a size smaller than normal for the middle portion of the cerebellum, along with an abnormal position for it. The fourth ventricle is also enlarged, as is the base of the skull. Hydrocephalus sometimes also occurs with DWM. When this happens, spinal fluid is blocked from flowing. This results from excessive fluid in and around the brain. Neurological problems can occur when pressures increase inside the skull and the head swells.

Holoprosencephaly

Soon after closure of the neural tube, the embryonic forebrain (prosencephalon) divides into two halves, or cerebral hemispheres. Failure of division is termed holoprosencephaly (literally "whole forebrain"). Holoprosencephaly, in its most severe case called alobar, results in a single-lobed brain structure. It is almost always accompanied by severe facial and cranial deformities along the midline, including **cleft lip**, **cleft palate**, fused eye sockets and a single eye (cyclopia), and deformities of the limbs, heart, gastrointestinal tract, and other internal organs. Most infants are either stillborn or die soon after birth. In some intermediate cases of holoprosencephaly, the brain's hemispheres partially divide. This form is called semilobar holoprosencephaly. In a third case called lobar holoprosencephaly, the brain has considerable separation of the hemispheres. Survivors, those

with less severe forms of the condition, suffer from neurological impairments and facial deformities, such as of the eyes, nose, and upper lip. In the least forms, the brain develops almost normally.

Lissencephaly

The normal ridges and valleys of the mature brain are formed after cells from the inside of the developing brain migrate to the outside and multiply. When these cells fail to migrate, the surface remains smooth, a rare, genetic condition called lissencephaly ("smooth brain"). Lissencephaly involves the cerebral cortex. Specifically, the normal folds (convolutions) of the cerebral cortex are not present. It causes the head to be abnormally small; what is called microcephaly. Lissencephaly occurs when the embryo does not develop normally due to defects in migration of nerve cells. It is often associated with facial abnormalities including a small jaw, a high forehead, a short nose, and low-set ears. The condition may also produce deformations in the fingers and hands, along with the toes. In addition, lissencephaly causes difficulties in swallowing, **muscle spasms**, seizures, and psychomotor retardation.

Schizencephaly

If damaged during growth, especially within the first 20 weeks, brain tissue may stop growing, while tissue around it continues to form. This causes an abnormal cleft or groove to appear on the surface of the brain, called schizencephaly (literally "split brain"). This cleft should not be confused with the normal wrinkled brain surface, nor should the name be mistaken for **schizophrenia**, a mental disorder. Generalized destruction of tissue or lack of brain development may lead to hydranencephaly, in which cerebrospinal fluid (CSF) fills much of the space normally occupied by the brain. Hydranencephaly is distinct from hydrocephalus, in which CSF accumulates within a normally formed brain, putting pressure on it and possibly causing skull expansion. Babies with schizencephaly usually have delays in learning skills such as language and speech. They normally have mental retardation, partial or complete **paralysis**, and a smaller-than-normal head. Some babies have unilateral clefts, in which clefts appear on only one hemisphere of the brain. They may be paralyzed on one side of their bodies; however, these babies may not have any degradation to their intelligence.

Megalencephaly

Excessive brain size is termed megalencephaly (literally "big brain"). Megalencephaly, is a condition described as an infant or child with an abnormally large, heavy head for his/her age and gender. It occurs more often in males than females. Megalencephaly is usually associated with brain that does not function properly. It is defined as any brain size above the 98th percentile (about two standard deviations) within the population. Some cases are familial (common among families, hereditary), and may be entirely benign. Others are due to metabolic or neurologic disease. Unilateral megalencephaly—sometimes also called hemimegalencephaly—is characterized by only one side of the brain being abnormally large. Megalencephaly is different from macrocephaly, which is also referred to as megacephaly or megalocephaly. Macrocephaly is a condition in which a large head does not necessarily mean is it considered "abnormally" large. Microcephaly, an opposite condition to macrocephaly, is considered a condition involving a smaller-than-average brain, but one that is not necessarily considered abnormal. It may be caused by failure of the brain to develop, or by intrauterine infection, drug toxicity, or brain trauma.

Causes and symptoms

Causes

Congenital brain defects may have genetic, infectious, toxic, or traumatic causes. In most cases, a certain cause cannot be identified.

GENETIC CAUSES. Some brain defects are caused by trisomy, the inclusion of a third copy of a chromosome normally occurring in pairs. Most trisomies occur because of improper division of the chromosomes during formation of eggs or sperm. Trisomy of chromosome 9 can cause some cases of Dandy-Walker and Chiari II malformation. Some cases of holoprosencephaly are caused by trisomy of chromosome 13, while others are due to abnormalities in chromosomes 7 or 18. Individual gene defects, either inherited or spontaneous, are responsible for other cases of congenital brain malformations.

DRUGS. Drugs known to cause congenital brain defects when used by the mother during critical developmental periods include:

- anticonvulsant drugs
- retinoic acid and tretinoin
- warfarin
- alcohol
- cocaine

WWW.BOOKBAZ.IR

KEY TERMS

Amniocentesis—Removal of fluid from the sac surrounding a fetus for purposes of diagnosis.

Cerebrospinal fluid—Fluid produced within the brain for nutrient transport and structural purposes. CSF circulates through the ventricles, open spaces within the brain, and drains through the membranes surrounding the brain.

Congenital—Defect present at birth.

Fetus—The unborn human, developing in a woman's uterus, from the eighth week after fertilization to birth.

OTHER. Other causes of congenital brain defects include:

- intrauterine infections, including cytomegalovirus, rubella, herpes simplex, and varicella zoster
- maternal diabetes mellitus
- maternal phenylketonuria
- fetal trauma

Symptoms

Besides the features listed, symptoms of congenital brain defects may include:

- Chiari II malformation: impaired swallowing and gag reflex, loss of the breathing reflex, facial paralysis, uncontrolled eye movements (nystagmus), impaired balance and gait.
- Dandy-Walker malformation: symptoms of hydrocephalus, lack of muscle tone or "floppiness," seizures, vomiting, spasticity, deafness, abnormal breathing patterns, irritability, visual impairment, deterioration of consciousness, paralysis.
- Lissencephaly: lack of muscle tone, irregular facial features, difficulty swallowing, seizures, developmental delay, spasticity, cerebral palsy.
- Hydranencephaly: visual impairment, deafness, blindness, paralysis, irritability, spasticity, seizures, temperature oscillations, lower-than-normal intelligence.
- Megalencephaly due to neurological or metabolic disease: mental retardation, seizures, brain cortex and spinal cord disfunction.

Diagnosis

Congenital brain defects are diagnosed either from direct **physical examination** or imaging studies including computed tomography (CT) scans and **magnetic resonance imaging** (MRI) scans. **Electroencephalography** (EEG) may be used to reveal characteristic abnormalities.

Prenatal diagnosis of neural tube defects causing anencephaly or meningomyelocele is possible through **ultrasound** examination and maternal blood testing for alpha-fetoprotein, which is almost always elevated. Ultrasound can also be used to diagnose Dandy-Walker and Chiari II malformations. **Amniocentesis** may reveal trisomies or other chromosomal abnormalities. Myelomeningocele is tested with a maternal serum alpha-fetoprotein (MSAFP) test, which tests the mother for alpha-fetoprotein (AFP), a protein that is produced by the fetus. Along with the MSAFP test, three other bloods tests may be used: human chorionic gonadotropin (HCG, a hormone produced by the placenta), Inhibin A (a hormone produced by the placenta), and Estriol (an estrogen produced by the fetus and placenta).

Treatment

Treatment generally varies depending on the type of defect. Meningomyelocele may be treated with surgery to close the open portion of the spinal cord. Surgery for encephalocele is possible only if there is a minimal amount of brain tissue protruding. Malformations associated with hydrocephalus (Dandy-Walker, Chiari II, and some cases of hydranencephaly) may be treated by installation of a drainage shunt for cerebrospinal fluid. Drugs may be used to treat some symptoms of brain defects, including seizures and spasticity.

Treatment for lissencephaly is unlikely to be successful in the most severe cases of it. However, support and care can be provided to the patient, and medication should control seizures. Treatment for megalencephaly has yet to be standardized. Treatment primarily depends on the symptoms and disabilities present with the patient.

Prognosis

Most congenital brain defects carry a very poor prognosis. Surgical treatment of meningomyelocele and encephalocele may be successful, with lasting neurological deficiencies, which vary in severity. Early treatment of hydrocephalus may prevent more severe brain damage. Infants and children with megalencephaly have a varied prognosis depending on the underlying cause and the related neurological disorder. For children with hemimegalencephaly, the prognosis is generally poor.

Prevention

Some cases of congenital brain defects can be prevented with good maternal **nutrition**, including **folic acid** supplements. Folic acid is a vitamin that has been shown to reduce the incidence of neural tube defects, both before and during pregnancy. Pregnant women should avoid exposure to infection, especially during the first trimester. Abstention from drugs and alcohol during pregnancy may reduce risk. **Genetic counseling** is advisable for parents who have had one child with anencephaly, since the likelihood of having another is increased.

Congenital defects *see* **Birth defects**

Congenital heart disease

Definition

Congenital **heart disease** (CHD), also called congenital heart defect, includes a variety of malformations (abnormalities) of the structure and function of the heart and/or its major blood vessels that occur before birth and are present at birth.

Description

Congenital heart disease occurs when the heart or blood vessels entering or leaving the heart do not develop normally before birth. Some infants are born with mild types of congenital heart disease that do not become apparent until later in life, but others need surgery as newborns or infants in order to survive. According to the U.S. National Institutes of Health (NIH), congenital heart disease is commonly divided into two major types: (1) cyanotic, in which the skin becomes bluish-purple due to a lack of oxygen and (2) non-cyanotic, in which the skin does not turn bluish-purple due to insufficient oxygen in the blood. The NIH lists the most common congenital heart diseases that occur. For cyanotic CHD, the list includes:

- Ebstein's anomaly (parts of the tricuspid value are abnormal)
- Hypoplastic left heart (parts of the left side of the heart, including the mitral valve, left ventricle, aortic valve, and aorta, have developed only partially)
- Pulmonary atresia (the pulmonary valve is malformed)

WWW.BOOKBAZ.IR

- Tetralogy of Fallot (usually one of the following is present: a hole is present in the right and left ventricles; a narrowing of the pulmonary outflow tract has occurred; the aorta has moved over the right ventricle instead of the left ventricle; or the wall of the right ventricle has thickened)
- Total anomalous pulmonary venous return (the four veins that take blood from the lungs to the heart are not attached to the left atrium)
- Transposition of the great vessels (the two major blood vessels, the aorta and the pulmonary artery, that take blood away from the heart are switched)
- Tricuspid atresia (the tricuspid heart valve has abnormally developed or did not develop)
- Truncus arteriosus (one blood vessel abnormally exits the right and left ventricles instead of the two blood vessels exiting the pulmonary artery and aorta)

The NIH lists the following common defects for non-cyanotic CHD:

- Aortic stenosis (also called aortic valve stenosis, the aortic valve develops abnormally and does not open fully)
- Atrial septal defect (the opening between the upper chambers of the heart does not close after birth; the hole allows blood to flow between these two chambers)
- Atrioventricular canal (also called endocardial cushion defect; the walls separating the four chambers of the heart do not form properly or are not present)
- Coarctation of the aorta (an abnormal narrowing of a portion of the aorta)
- Patent ductus arteriosus (the ductus arteriosus does not close after birth, which allows blood to flow between the pulmonary artery and the aorta)
- Pulmonic stenosis (also called pulmonary valve stenosis; the pulmonary valve did not develop properly; it does not open as wide as normal and reduces blood flow to the lungs)
- Ventricular septal defect (one or more holes develop in the wall that separates the left and right ventricles of the heart)

Anatomy of the heart

The heart has four compartments or chambers, a left and right atrium above a left and right ventricle. These chambers prevent blood carrying oxygen (oxygenated blood) from mixing with blood that has already given up its oxygen to cells (deoxygenated blood). Blood moves through the heart in a specific pattern. Deoxygenated blood returning from the body enters the right atrium. It moves through a valve into the right ventricle. When the right ventricle contracts, blood is pumped through another valve and is carried to the lungs where it picks up oxygen. The newly oxygenated blood returns to the heart and enters the left atrium. It flows through a valve into the left ventricle and is then pumped through another valve to the aorta, a large artery. From the aorta, oxygenated blood is distributed to the rest of the body. Congenital heart disease causes disruption or inefficiency in this pattern.

Heart Defects

There are many congenital heart defects, but all of them fall into one of four major categories:

- Obstruction defects are those defects that obstruct the flow of blood to the heart, lungs, or the nearby blood vessels. This can be caused by narrowed or malformed blood vessels or heart valves.
- Cyanotic defects are those that allow oxygenated and deoxygenated blood to mix. This can be caused by holes in the partitions (septa) between chambers or leaky valves that separate the chambers.
- Major structural defects involve missing or underdeveloped heart chambers or incorrectly located blood vessels.
- Other defects consist of various arrhythmias, which are defects in the timing of contractions of the various chambers so that the chambers do not fill and empty completely; the heartbeat may be too fast, too slow, or uncoordinated.

OBSTRUCTION DEFECTS.. When heart valves, arteries, or veins are narrowed, they partly or completely block the flow of blood. The most common obstruction defects are **pulmonary valve stenosis**, **aortic valve stenosis**, and **coarctation of the aorta**. Bicuspid aortic valve and subaortic stenosis are less common.

Stenosis is a narrowing of the valves or arteries. In pulmonary stenosis, the pulmonary valve does not open properly, forcing the right ventricle to work harder. In aortic stenosis, the improperly formed aortic valve is narrowed. As the left ventricle works harder to pump blood through the body, it becomes enlarged. In coarctation of the aorta, the aorta is constricted, reducing the flow of blood to the lower part of the body and increasing blood pressure in the upper body.

A bicuspid aortic valve has only two flaps instead of three, which can lead to stenosis in adulthood. Subaortic stenosis is a narrowing of the left ventricle

below the aortic valve, which limits the flow of blood from the left ventricle.

CYANOTIC DEFECTS. Heart defects that cause a decreased, inadequate amount of oxygen in blood pumped to the body are called cyanotic defects. When a baby is born with a hole in the septum (the wall separating the right and left sides of the heart), blood can leak from one chamber to another, allowing oxygenated and deoxygenated blood to mix. This causes less oxygen to be delivered to the body. Major leakage can lead to enlargement of the heart and failing circulation. The most common types of septal defects are **atrial septal defect** (ASD), an opening between the two upper heart chambers, and **ventricular septal defect** (VSD), an opening between the two lower heart chambers. Ventricular septal defect accounts for about 15% of all cases of congenital heart disease in the United States.

Patent ductus arteriosus (PDA) refers to the opening of a temporary blood vessel (ductus) that carries blood from the heart to the aorta before birth, allowing blood to bypass the lungs, which are not yet functional. The ductus should close spontaneously in the first few hours or days after birth. When it does not close in the newborn, some of the blood that should flow through the aorta returns to the lungs. Patent ductus arteriosus is common in premature babies but rare in full-term babies. It also has been associated with mothers who had German **measles** (**rubella**) while pregnant.

Ebstein's anomaly is a rare congenital syndrome that causes malformed tricuspid valve leaflets, which allow blood to leak between the right ventricle and the right atrium. It also may cause a hole in the wall between the left and right atrium. Treatment often involves repairing the tricuspid valve.

Other cyanotic defects, including truncus arteriosus, total anomalous pulmonary venous return, and **tetralogy of Fallot**, result in blue discoloration of the skin due to low oxygen levels. About 10% of cases of congenital heart disease in the United States are tetralogy of Fallot, which includes four defects. The major defects are a large hole between the ventricles, which allows oxygen-poor blood to mix with oxygen-rich blood, and narrowing at or beneath the pulmonary valve. The other defects are an overly muscular right ventricle and an aorta that lies over the ventricular hole.

MAJOR STRUCTURAL DEFECTS. In transposition (reversal of position) of the great arteries, the pulmonary artery and the aorta are reversed, causing oxygenated blood to recirculate to the lungs while deoxygenated blood goes to the rest of the body. In tricuspid atresia, the baby lacks a triscupid valve, and blood cannot flow properly from the right atrium to the right ventricle.

Hypoplastic left heart syndrome, a condition in which the left side of the heart is underdeveloped, is rare, but it is the most serious type of congenital heart disease. With this condition, blood reaches the aorta only from the ductus, which then closes normally within a few days of birth. In hypoplastic left heart syndrome, the baby seems normal at birth, but as the ductus closes, blood cannot reach the aorta and circulation fails.

Infants born with DiGeorge sequence can have heart defects such as a malformed aortic arch and tetralogy of Fallot. Researchers believe DiGeorge sequence most often is caused by mutations in genes in the region 22q11.

OTHER DEFECTS. Brugada syndrome is another rare congenital heart defect that appears in adulthood and may cause sudden death if untreated. Symptoms, which include rapid, uneven heartbeat, often appear at night. Scientists contend that Brugada syndrome is caused by mutations in the gene SCN5A, which involves cardiac **sodium** channels.

Marfan syndrome is a connective tissue disorder that causes tears in the aorta. Since the disease also causes excessive bone growth, most Marfan syndrome patients are over 6 ft (1.8 m) tall. In athletes, and others, it can lead to sudden death. Researchers believe the defect responsible for Marfan's syndrome is found in gene FBN1, on chromosome 15.

Demographics

According to WebMD.com, approximately one in 100 children develop congenital heart disease while a fetus in the womb (uterus). The U.S. Centers for Disease Control and Prevention (CDC) and the Children's Heart Foundation (CHF) state that congenital heart defects are the most common type of birth defect in the United States, with about 40,000 babies being effected each year (about 1% of all births). About half of these cases require medical treatment; the rest correct (resolve) spontaneously shortly after birth or are so mild as to need no treatment or to go undetected. The CHF states that thousands of babies each year do not make it to their first birthday due to congenital **birth defects**, and thousands more do not reach adulthood. However, the Adult Congenital Heart Association states that 90% of children born with a heart defect survive into adulthood.

WWW.BOOKBAZ.IR

More than 1.4 million people with congenital heart defects were living in the United States in 2007. (The CDC confirmed in 2011 that no population-based tracking program existed to substantiate this figure so other methods were used to estimate such data for children and adults.) The CDC stated in 2011 that "there likely are nearly 1 million adults in the United States living with a congenital heart defect." In 2012, the American Heart Association released its *Heart Disease and Stroke Statistics*, which stated that over 1 million adults lived with congenital heart disease in the United States.

The CDC has also found that congenital heart defects are increasing in the United States, especially with regards to milder forms of the condition. The organization stated that the most common type of heart defect is ventricular septal defect. In addition, congenital heart defects are a leading cause of "birth defect-associated infant illness and death."

Economically, congenital heart defects cost the United States approximately $2.2 billion each year for inpatient surgery to repair such defects. According to the CHF, "CHD research is grossly under-funded relative to the prevalence of the disease." Further, "Of every dollar the government spends on medical funding only a fraction of a penny is directed toward congenital heart defect research." Internationally, the National Heart, Lung, and Blood Institute (NHLBI) stated, "Congenital Heart Defects are a serious and underappreciated global health problem."

Causes and symptoms

In most cases, the causes of congenital heart disease are unknown. Genetic, environmental, and lifestyle factors all can be involved. The likelihood of having a child with congenital heart disease increases if a parent or other close relative has congenital heart disease or if there is a family history of early **sudden cardiac death**. Congenital heart disease is common in children with other genetic disorders that affect many organ systems, such as **Down syndrome**. In addition, researchers have identified about ten genetic changes (mutations) that cause some type of congenital heart disease but no widespread symptoms.

According to the Society for Cardiovascular **Angiography** and Interventions (SCAI), the following non-genetic risk factors contribute to congenital heart disease:

- smoking tobacco products of the mother during pregnancy
- obesity of the mother
- exposure of the mother to various air pollutants, pesticides, and solvents
- low levels of folic acid ingestion by the mother during pregnancy
- lack of control of diabetes during pre-pregnancy and pregnancy of the mother

During **pregnancy**, viral infections such as German measles can result in congenital heart disease in the newborn. Women with diabetes and **phenylketonuria** (PKU, an inherited liver disorder) also are at higher risk of having children with congenital heart defects. Some cases of congenital heart disease result from the mother's excessive use of alcohol or taking illegal street drugs, such as cocaine or methamphetamines, during pregnancy. The mother's use of certain anticonvulsant (anti-seizure) drugs or dermatologic drugs (e.g., isotretinon [Accutane and other brand names], thalidomide) during pregnancy also can cause congenital heart disease.

Symptoms of congenital heart disease differ depending on the particular condition. However, in general, symptoms include **shortness of breath**, difficulty feeding in infancy, excessive sweating, **cyanosis** (bluish discoloration of the skin), heart murmur, respiratory infections that recur excessively, stunted growth, and limbs and muscles that are underdeveloped.

Symptoms of specific types of congenital heart disease are as follows:

- Patent ductus arteriosus: quick tiring, slow growth, susceptibility to pneumonia, rapid breathing. If the ductus is small, there are no symptoms.
- Hypoplastic left heart syndrome: ashen color, rapid and difficult breathing, inability to eat.
- Obstruction defects: cyanosis (skin that is discolored blue), chest pain, tiring easily, dizziness or fainting, congestive heart failure, and high blood pressure.
- Septal defects: difficulty breathing, stunted growth. Sometimes there are no symptoms.
- Cyanotic defects: cyanosis, sudden rapid breathing or unconsciousness, and shortness of breath and fainting during exercise.

Diagnosis

Echocardiography and cardiac **magnetic resonance imaging** (MRI) commonly are used to confirm congenital heart disease when it is suggested by the symptoms and **physical examination**. These are non-invasive (nothing enters the body) tests. An echocardiograph displays an image of the heart that is formed by sound waves. It may detect valve and other heart problems. Fetal echocardiography is used to help

diagnose congenital heart disease in utero, usually after 20 weeks of pregnancy. Between 10 and 14 weeks of pregnancy, physicians also may use an **ultrasound** to look for a thickness at the nuchal translucency, a pocket of fluid in back of the embryo's neck, which may indicate a cardiac defect. Most congenial heart defects are discovered with the use of a pregnancy ultrasound.

Cardiac MRI, a scanning method that uses magnetic fields and radio waves, can help physicians evaluate congenital heart disease but is not always necessary. Physicians also may use a chest x ray to look at the size and location of the heart and lungs, or an electrocardiograph (ECG), which measures electrical impulses to create a graph of the heartbeat. After birth, pulse oximetry is a noninvasive way to measure the amount of oxygen in the blood (a sensor is clipped on a finger or toe). **Cardiac catheterization**, an invasive test done under **anesthesia**, allows a dye to be inserted into the heart so that blood circulation through the heart can be seen on an x ray. Cardiac catheterization also can measure pressure in the heart chambers to determine if there is blood mixing or leakage between heart chambers.

Treatment

Congenital heart disease may be treated various ways depending on the type of problem. Generally, when treatment is advised, drugs and/or surgery are used. Drugs used include **diuretics**, which increase the excretion water and salts, and **digoxin**, which strengthens the contraction of the heart, slows the heartbeat, and removes fluid from tissues.

Surgical procedures seek to repair the defect as much as possible and restore circulation to as close to normal as possible. Sometimes, multiple surgical procedures are necessary. Surgical procedures include arterial switch, balloon atrial septostomy, **balloon valvuloplasty**, Damus-Kaye-Stansel procedure, Fontan procedure, pulmonary artery banding, Ross procedure, shunt procedure, and venous switch or intra-atrial baffle.

Arterial switch, to correct **transposition of the great arteries**, involves connecting the aorta to the left ventricle and connecting the pulmonary artery to the right ventricle. Balloon atrial septostomy, also done to correct transposition of the great arteries, enlarges the atrial opening during heart catheterization. Balloon valvuloplasty uses a balloon-tipped catheter to open a narrowed heart valve, improving the flow of blood in pulmonary stenosis. It is sometimes used in aortic stenosis. Transposition of the great arteries also can be corrected by the Damus-Kaye-Stansel procedure, in which the pulmonary artery is cut in two and connected to the ascending aorta and the farthest section of the right ventricle.

For tricuspid atresia and pulmonary atresia, the Fontan procedure connects the right atrium to the pulmonary artery directly or with a conduit, and the atrial defect is closed. Pulmonary artery banding, narrowing the pulmonary artery with a band to reduce blood flow and pressure in the lungs, is used for ventricular septal defect, atrioventricular canal defect, and tricuspid atresia. Later, the band can be removed, and the defect corrected with open-heart surgery.

To correct aortic stenosis, the Ross procedure grafts the pulmonary artery to the aorta. For tetralogy of Fallot, tricuspid atresia, or pulmonary atresia, the shunt procedure creates a passage between blood vessels, sending blood into parts of the body that need it. For transposition of the great arteries, venous switch creates a tunnel inside the atria to redirect oxygen-rich blood to the right ventricle and aorta and venous blood to the left ventricle and pulmonary artery.

When surgery is not a viable option to correct the problem, some patients undergo a heart transplant. Children with congenital heart disease require lifelong monitoring, even after successful surgery. The American Heart Association recommends regular dental check-ups and preventive use of **antibiotics** to protect patients from heart infection (**endocarditis**). Many patients do not understand the risk of endocarditis. Since children with congenital heart disease often have slower growth, good **nutrition** is important. Physicians also may limit their athletic activity.

Prognosis

The outlook for children with congenital heart disease improved markedly in the late twentieth and early twenty-first centuries. Many types of congenital heart disease that would have been fatal in the past began to be treated successfully. Because many children with these defects survive into adulthood, they require continued medical observation as they mature. Research on diagnosing heart defects when the fetus is in the womb may lead to future treatment to correct some defects before birth. Promising new prevention methods and treatments include genetic screening and the cultivation of cardiac tissue in the laboratory that might be useful in repairing some congenital heart defects. As scientists continue to advance the study of genetics, they also improve their understanding of genetic causes of many congenital heart diseases.

WWW.BOOKBAZ.IR

KEY TERMS

Aorta—The main artery located above the heart that pumps oxygenated blood out into the body. Many congenital heart defects affect the aorta.

Atrium (plural: atria)—The right or left upper chamber of the heart.

Cardiac catheterization—A diagnostic procedure (using a catheter inserted through a vein and threaded through the circulatory system to the heart) that provides a comprehensive examination of how the heart and its blood vessels are functioning.

Congenital—Refers to a disorder that is present at birth.

Cyanotic—Marked by bluish discoloration of the skin due to a lack of oxygen in the blood. It is one of the types of congenital heart disease.

Ductus—The blood vessel that joins the pulmonary artery and the aorta. When the ductus does not close at birth, it causes a type of congenital heart disease called patent ductus arteriosus.

Echocardiogram—A noninvasive imaging procedure used to create a picture of the heart's movement, valves, and chambers.

Electrocardiograph (ECG, EKG)—A test used to measure electrical impulses coming from the heart in order to gain information about its structure or function.

Endocarditis—Infection of the heart endocardium tissue, the inner most tissue and structures of the heart.

Hypoplastic—Incomplete or underdevelopment of a tissue or organ. Hypoplastic left heart syndrome is the most serious type of congenital heart disease.

Marfan syndrome—An inherited condition that affects connective tissue throughout the body, including weakening the connective tissue found in arteries.

Neuchal translucency—A pocket of fluid at the back of an embryo's neck visible via ultrasound that, when thickened, may indicate the infant will be born with a congenital heart defect.

Septal—Relating to the septum, the thin muscle wall dividing the right and left sides of the heart. Holes in the septum are called septal defects.

Stenosis (plural: stenoses)—The narrowing or constriction of an opening or passageway in the body.

Ventricle—A lower pumping chamber of the heart. There are two ventricles, right and left. The right ventricle pumps oxygen-poor blood to the lungs to be reoxygenated. The left ventricle pumps oxygen-rich blood to the body.

Prevention

Congenital heart disease is a hereditary disease, and as such, certain genes are responsible for its occurrence. Thus, CHD cannot be prevented. It runs in families, and many family members may be affected by it. For families in which CHD is common, a health professional may be able to provide genetic screening. Women of childbearing years should be especially concerned with congenital heart disease. Prenatal care is essential for such pregnant women to minimize the risks to their unborn babies. They should do the following during their pregnancy:

- avoid illegal drugs and alcohol
- regularly visit the family doctor and/or obstetrician
- have blood tests taken early in the pregnancy to determine their status to rubella (measles)
- avoid exposure to rubella during the pregnancy
- maintain a healthy blood sugar level if diabetic

People who have congenital heart disease and have had their heart repaired or placed in surgery are at increased risk for endocarditis (the inflammation of the inner layer of the heart). To minimize the risk for endocarditis, the Mayo Clinic has advised individuals to take the following measures:

- Report to all doctors and dentists that they have congenital heart disease. They may want to carry a card with this information.
- Call their doctor if they have symptoms of an infection (sore throat, general body aches, fever).
- Take good care of their teeth and gums to prevent infections. See their dentist for regular visits.
- Take antibiotics according to the American Heart Association guidelines before they undergo a procedure that may cause bleeding such as dental work, invasive tests (any test that may involve blood or bleeding), and most major or minor surgeries. Check with their doctor about the type and amount of antibiotics that they should take.

Congenital hip dysplasia

Definition

A condition of abnormal development of the hip, resulting in hip joint instability and potential dislocation of the thigh bone from the socket in the pelvis. This condition has been more recently termed developmental hip dysplasia, as it often develops over the first few weeks, months, or years of life.

Description

Congenital hip dysplasia is a disorder in children that is either present at birth or shortly thereafter. During gestation, the infant's hip should be developing with the head of the thigh bone (femur) sitting perfectly centered in its shallow socket (acetabulum). The acetabulum should cover the head of the femur as if it were a ball sitting inside of a cup. In the event of congenital hip dysplasia, the development of the acetabulum in an infant allows the femoral head to ride upward out of the joint socket, especially when weight bearing begins.

Causes and symptoms

Clinical studies show a familial tendency toward hip dysplasia, with more females affected than males. This disorder is found in many cultures around the world. However, statistics show that the Native American population has a high incidence of hip dislocation. This has been documented to be due to the common practice of swaddling and using cradleboards for restraining the infants. This places the infant's hips into extreme adduction (brought together). The incidence of congenital hip dysplasia is also higher in

WWW.BOOKBAZ.IR

infants born by caesarian and breech position births. Evidence also shows a greater chance of this hip abnormality in the first born compared to the second or third child. Hormonal changes within the mother during **pregnancy**, resulting in increased ligament laxity, is thought to possibly cross over to the placenta and cause the baby to have lax ligaments while still in the womb. Other symptoms of complete dislocation include a shortening of the leg and limited ability to abduct the leg.

Diagnosis

Because the abnormalities of this hip problem often vary, a thorough **physical examination** is necessary for an accurate diagnosis of congenital hip dysplasia. The hip disorder can be diagnosed by moving the hip to determine if the head of the femur is moving in and out of the hip joint. One specific method, called the Ortolani test, begins with each of the examiner's hands around the infant's knees, with the second and third fingers pointing down the child's thigh. With the legs abducted (moved apart), the examiner may be able to discern a distinct clicking sound with motion. If symptoms are present with a noted increase in abduction, the test is considered positive for hip joint instability. It is important to note this test is only valid a few weeks after birth.

The Barlow method is another test performed with the infant's hip brought together with knees in full bent position. The examiner's middle finger is placed over the outside of the hipbone while the thumb is placed on the inner side of the knee. The hip is abducted to where it can be felt if the hip is sliding out and then back in the joint. In older babies, if there is a lack of range of motion in one hip or even both hips, it is possible that the movement is blocked because the hip has dislocated and the muscles have contracted in that position. Also in older infants, hip dislocation is evident if one leg looks shorter than the other.

X-ray films can be helpful in detecting abnormal findings of the hip joint. X rays may also be helpful in finding the proper positioning of the hip joint for treatments of casting. **Ultrasound** has been noted as a safe and effective tool for the diagnosis of congenital hip dysplasia. Ultrasound has advantages over x rays, as several positions are noted during the ultrasound procedure. This is in contrast to only one position observed during the x ray.

Treatment

The objective of treatment is to replace the head of the femur into the acetabulum and, by applying constant pressure, to enlarge and deepen the socket. In the past, stabilization was achieved by placing rolled cotton diapers or a pillow between the thighs, thereby keeping the knees in a frog like position. More recently, the Pavlik harness and von Rosen splint are commonly used in infants up to the age of six months. A stiff shell cast may be used, which achieves the same purpose, spreading the legs apart and forcing the head of the femur into the acetabulum. In some cases, in older children 6–18 months, surgery may be necessary to reposition the joint. Also at this age, the use of closed manipulation may be applied successfully, by moving the leg around manually to replace joint. Operations are not only performed to reduce the dislocation of the hip, but also to repair a defect in the acetabulum. A cast is applied after the operation to hold the head of the femur in the correct position. The use of a home **traction** program is now more common. However, after the age of eight years, surgical procedures are primarily done for **pain** reduction measures only. Total hip surgeries may be inevitable later in adulthood.

Alternatives

Nonsurgical treatments include **exercise** programs, orthosis (a force system, often involving braces), and medications. A physical therapist may develop a program that includes strengthening, range-of-motion exercises, pain control, and functional activities. **Chiropractic** medicine may be helpful, especially the procedures of closed manipulations, to reduce the dislocated hip joint.

Prognosis

Unless corrected soon after birth, abnormal stresses cause malformation of the developing femur, with a characteristic limp or waddling gait. If cases of congenital hip dysplasia go untreated, the child will have difficulty walking, which could result in life-long pain. In addition, if this condition goes untreated, the abnormal hip positioning will force the acetabulum to locate to another position to accommodate the displaced femur.

KEY TERMS

Acetabulum—The large cup-shaped cavity at the junction of pelvis and femur or thigh bone.

Orthosis—A force system designed to control or correct or compensate for a bone deformity, deforming forces, or forces absent from the body.

Prevention

Prevention includes proper prenatal care to determine the position of the baby in the womb. This may be helpful in preparing for possible breech births associated with hip problems. Avoiding excessive and prolonged infant hip adduction may help prevent strain on the hip joints. Early diagnosis remains an important part of prevention of congenital hip dysplasia.

Congenital lobar emphysema

Definition

Congenital lobar **emphysema** is a chronic disease that causes respiratory distress in infants.

Description

Congenital lobar emphysema, also called infantile lobar emphysema, is a respiratory disease that occurs in infants when air enters the lungs but cannot leave easily. The lungs become over-inflated, causing respiratory function to decrease and air to leak out into the space around the lungs.

Half of the cases of congenital lobar emphysema occur in the first four weeks of life, and three-quarters occur in infants less than six months old. Congenital lobar emphysema is more common in boys than in girls.

Each person has two lungs, right and left. The right lung is divided into three sections, called lobes, and the left lung into two lobes. Congenital lobar emphysema usually affects only one lobe, and this is usually an upper lobe. It occurs most frequently in the left upper lobe, followed by the right middle lobe.

Causes and symptoms

The cause of congenital lobar emphysema often cannot be identified. The airway may be obstructed or the infant's lungs may not have developed properly. Congenital lobar emphysema is almost never of genetic origin.

KEY TERMS

Congenital—A disease or condition that is present at birth.

Emphysema—A condition in which the air sacs in the lungs become overinflated, causing a decrease in respiratory function.

Lobar—Relating to a lobe, a rounded projecting part of the lungs.

Symptoms of congenital lobar emphysema include:

- shortness of breath
- wheezing
- lips and fingernail beds that have a bluish tinge

Diagnosis

Congenital lobar emphysema is usually identified within the first two weeks of the infant's life. It is diagnosed by respiratory symptoms and a chest x ray, which shows the over-inflation of the affected lobe and may show a blocked air passage.

Treatment

For infants with no, mild, or intermittent symptoms, no treatment is necessary. For more serious cases of congenital lobar emphysema, surgery is necessary, usually a **lobectomy** to remove the affected lung lobe.

Alternatives

Alternative treatments that may be helpful for congenital lobar emphysema are aimed at supporting and strengthening the patient's respiratory function. Vitamin and mineral supplementation may be recommended as may herbal remedies such as lobelia (*Lobelia inflata*) that strengthen the lungs and enhance their elasticity. Homeopathic constitutional care may also be beneficial for this condition.

Prognosis

Surgery for congenital lobar emphysema has excellent results.

Prevention

Congenital lobar emphysema cannot be prevented.

Congenital thymic hypoplasia *see* **DiGeorge syndrome**

Congenital ureter anomalies

Definition

The ureter drains urine from the kidney into the bladder. It is not simply a tube but an active organ that propels urine forward by muscular action. It has a valve at its bottom end that prevents urine from flowing backward into the kidney. Normally there is one ureter on each side of the body for each kidney. However, among the many abnormalities of ureteral development, duplication is quite common. Ureters may also be malformed in a variety of ways—some harmful, others not.

Description

The urogenital system, for some reason, is more likely than any other to have **birth defects**, and they can occur in endless variety. Ureters can be duplicated completely or partially, they can be in the wrong place, they can be deformed, and they can end in the wrong place. The trouble these abnormalities bring is directly related to their effect on the flow of urine. As long as urine flows normally through them, and only in one direction, no harm is done.

- Duplication of ureters is quite common, either in part or completely. Kidneys are sometimes duplicated as well. Someone may have four kidneys and four ureters or two kidneys, half of each drained by a separate ureter, or a single kidney with two, three, or four ureters attached. As long as urine can flow easily in the correct direction, such malformations may never be detected. If, however, one of the ureters has a dead end, a stricture or stenosis (narrowing), or a leaky ureterovesical valve (valve between the ureter and bladder), infection is the likely result.
- Stricture or stenosis of a ureter prevents urine from flowing freely. Whenever flow is obstructed in the body—urine, bile, mucus, or any other liquid—infection follows. Ureters can be obstructed anywhere along their course, though the ureterovesical valve is the most common place.
- A ureter may have an ectopic (out of place) orifice (opening)–it may enter the bladder, or even another structure, where it does not belong and therefore without an adequate valve to control reflux.
- The primary ureter, or a duplicate, may not even reach the bladder, but rather terminate in a dead end. Urine will stagnate there and eventually cause infection.
- A ureter can be perfectly normal but in the wrong place, such as behind the vena cava (the large vein in the middle of the abdomen). A so-called retrocaval ureter may be pinched by the vena cava so that flow is hindered. Other aberrant locations may also lead to compression and impaired flow.

Besides infection, urine that backs up will cause the ureter and the kidney to dilate. Eventually, the kidney will stop functioning because of the back pressure. This condition is called hydronephrosis—a kidney swollen with urine.

Causes and symptoms

The causes of birth defects are multiple and often unknown. Furthermore, the precise cause of specific birth defects has only rarely been identified. Such is the case with congenital ureteral anomalies.

Practically the only symptom generated by ureteral abnormalities is **urinary tract infection**. A lower tract infection—in the bladder—is called **cystitis**. In children, it may cause **fever** and systemic symptoms, but in adults it causes only cloudy, burning, and frequent urine. Upper tract infections, on the other hand, can be serious for both adults and children, causing high fevers, back **pain**, severe generalized discomfort, and even leading to kidney failure or septicemia (infection spreading throughout the body by way of the blood stream).

In rare cases, urine from an ectopic ureter will bypass the bladder and dribble out of the bottom somewhere, through a natural orifice like the vagina or a completely separate unnatural opening.

Diagnosis

Serious or recurrent urinary infections will prompt a search for underlying abnormalities. **Cystoscopy** (looking into the bladder with a thin

KEY TERMS

Congenital—Present at birth.

Contrast agent—A chemical or other substance placed in the body to show structures that would not otherwise be visible on x ray or other imaging studies.

Cystoscopy—Looking into the urinary bladder with a thin telescope-like instrument.

Ectopic—Out of place.

Septicemia—A serious whole body infection spreading through the blood stream.

Ureterovesical valve—A sphincter (an opening controlled by a circular muscle), located where the ureter enters the bladder, that keeps urine from flowing backward toward the kidney.

Urogenital—Both the urinary system and the sexual organs, which form together in the developing embryo.

telescope-like instrument) and x rays with a contrast agent to illuminate the urinary system will usually identify the defect. **Computed tomography scans** (CT) and **Magnetic resonance imaging** (MRI) may provide additional information. Urine cultures to identify the infecting germs will be repeated frequently until the problem is corrected.

Treatment

Sometimes the recurring infections caused by flow abnormalities can be treated with repeated and changing courses of **antibiotics**. Over time, the infecting germs develop resistance to most treatments, especially the safer ones. If it can be done with acceptable risk, it is better to repair the defect surgically. Urologists have an arsenal of approaches to urine drainage that range from simply reimplanting a ureter into the bladder, in such a way that an effective valve is created, to building a new bladder out of a piece of bowel.

Alternatives

There are botanical and homeopathic treatments available for urinary tract infection. None can take the place of correcting a problem that is occurring because of a malformed or dysfunctional organ system. Once correction of the cause is addressed and there is unimpeded flow of urine, adequate fluid intake can contribute to prevention of future infections.

Prognosis

As long as damage to the kidneys from infection or back pressure has not become significant, the surgical repair of troublesome ureteral defects produces excellent long-term results in the great majority of cases. Monitoring for recurrent infections is always a good idea, and occasional checking of kidney function will detect hidden ongoing damage.

Congestive cardiomyopathy

Definition

Cardiomyopathy is an ongoing disease process that damages the muscle wall of the lower chambers of the heart. Congestive cardiomyopathy is the most common form of cardiomyopathy. In congestive cardiomyopathy, also called dilated cardiomyopathy, the walls of the heart chambers stretch (dilate) to hold a greater volume of blood than normal. Congestive cardiomyopathy is the final stage of many heart diseases and the most common condition resulting in **congestive heart failure**.

Description

About 50,000 Americans develop cardiomyopathy each year. Of those, 87% have congestive cardiomyopathy. Primary cardiomyopathy accounts for only 1% of all deaths from **heart disease**.

When the heart muscle is damaged by a disease process, it cannot pump enough blood to meet the body's needs. Uninjured areas of the walls of the two lower heart chambers (called ventricles) stretch to make up for the lost pumping action. At first, the enlarged chambers allow more blood to be pumped with less force. The stretched muscle can also contract more forcefully. Over time, the heart muscle continues

WWW.BOOKBAZ.IR

to stretch, ultimately becoming weaker. The heart is forced to work harder to pump blood by beating faster. Eventually it cannot keep up, and blood backs up into the veins, legs, and lungs. When this happens, the condition is called congestive **heart failure**.

Congestive cardiomyopathy usually affects both ventricles. Blood backed up into the lungs from the left ventricle causes fluid to congest the lung tissue. This is called **pulmonary edema**. When the right ventricle fails to pump enough blood, blood backs up into the veins causing **edema** in the legs, feet, ankles, and abdomen.

Causes and symptoms

Congestive cardiomyopathy may be caused by a number of conditions. Cardiomyopathy with a known cause is called secondary cardiomyopathy. When no cause can be identified, it is called primary cardiomyopathy or idiopathic cardiomyopathy. About 80% of all cases of cardiomyopathy do not have a known cause. Many heart specialists think that many cases of idiopathic congestive cardiomyopathy may be caused by a viral infection. Because cardiomyopathy may occur many years after a viral infection and viruses sometimes go undetected in laboratory tests, it is difficult to know if a virus is the cause. Some people have a weak heart from advanced **coronary artery disease** that causes heart muscle damage. This is sometimes called ischemic cardiomyopathy.

Conditions that can cause congestive cardiomyopathy are:

- coronary artery disease
- infections
- noninfectious inflammatory conditions
- alcohol and other drugs or toxins
- hypertension
- nutritional and metabolic disorders
- pregnancy

Coronary artery disease is one of the most common causes of congestive cardiomyopathy. In coronary artery disease, the arteries supplying blood to the heart become narrowed or blocked. When blood flow to an area of the heart is completely blocked, the person has a **heart attack**. The heart muscle is damaged when its blood supply is reduced or blocked. Significant recurrent muscle damage can occur silently. This damage can lead to congestive cardiomyopathy.

Infections caused by bacteria, viruses, and other microorganisms can involve the heart, causing inflammation of the heart muscle (**myocarditis**). The inflammation may damage the heart muscle and cause congestive cardiomyopathy. In the United States, the coxsackievirus B is the most common cause of viral congestive cardiomyopathy.

Myocarditis can also be caused by noninfectious disorders. For example, the conditions **sarcoidosis**, granulomatous myocarditis, and Wegener's granulomatosis cause inflammation and tissue death in the heart muscle.

Years of drinking excessive amounts of alcohol can weaken the heart muscle, leading to congestive cardiomyopathy. Other drugs and toxins, such as cocaine, pesticides, and other chemicals, may have the same effect.

High blood pressure (**hypertension**) puts extra pressure on blood vessels and the heart. This increased pressure makes the heart work harder to pump blood, which may thicken and damage the chamber walls.

Severe nutritional deficiencies can weaken the heart muscle and affect its pumping ability. Certain disorders of metabolism, including **diabetes mellitus** and thyroid disorders, can also lead to congestive cardiomyopathy.

Occasionally, inflammation of the heart muscle and congestive cardiomyopathy may develop late in **pregnancy** or shortly after a woman gives birth. This type of congestive cardiomyopathy is called peripartum cardiomyopathy. The cause of congestive cardiomyopathy in pregnancy is not known.

Congestive cardiomyopathy usually is a chronic condition, developing gradually over time. Patients with early congestive cardiomyopathy may not have symptoms. The most common symptoms are **fatigue** and **shortness of breath** on exertion. Unfortunately, **sudden cardiac death** is not uncommon with this condition. It stems from irregular heart rhythms in the ventricles (ventricular **arrhythmias**).

Patients with more advanced congestive cardiomyopathy may also have chest or abdominal pains, extreme tiredness, **dizziness**, and swelling of the legs and ankles.

Diagnosis

Diagnosis of congestive cardiomyopathy is based upon:

- symptoms
- medical history
- physical examination
- chest x ray
- electrocardiogram (ECG; also called EKG)
- echocardiogram
- cardiac catheterization

The diagnosis is based on the patient's symptoms, a complete **physical examination**, and tests that detect abnormalities of the heart chambers. The physician listens to the heart with a stethoscope to detect abnormal heart rhythms and heart sounds. A heart murmur might mean that the heart valves are not closing properly due to the ventricles being enlarged.

A chest x ray can show if the heart is enlarged and if there is fluid in the lungs. Abnormalities of heart valves and other structures may also be seen on a chest x ray.

An electrocardiogram provides a record of electrical changes in the heart muscle during the heartbeat. It gives information on the heart rhythm and can show if the heart chamber is enlarged. An ECG can detect damage to the heart muscle and the amount of damage.

Echocardiography uses sound waves to make images of the heart. These images can show if the heart wall or chambers are enlarged and if there are any abnormalities of the heart valves. Echocardiography can also evaluate the pumping efficiency of the ventricles.

Cardiac catheterization usually is only used if a diagnosis cannot be made with other methods. In cardiac catheterization, a small tube (called a catheter) is inserted into an artery and passed into the heart. It is used to measure pressure in the heart and the amount of blood pumped by the heart. A small tissue sample of the heart muscle can be removed through the catheter for examination under a microscope (biopsy). This biopsy can show the type and amount of damage to the heart muscle.

Treatment

When a patient is diagnosed with congestive cardiomyopathy, physicians try to find out the cause. If coronary artery disease is not the culprit, in most other cases a cause is not identified. When a condition responsible for the congestive cardiomyopathy is diagnosed, treatment is aimed at correcting the underlying condition. Congestive cardiomyopathy caused by drinking excess alcohol or by drugs or toxins can be treated by eliminating the alcohol or toxin completely. In some cases, the heart may recover after the toxic substance is removed from the body. Bacterial myocarditis is treated with an antibiotic to eliminate the bacteria.

There is no cure for idiopathic congestive cardiomyopathy. Medicines are given to reduce the workload of the heart and to relieve the symptoms.

One or more of the following types of medicines may be prescribed for congestive cardiomyopathy:

- digitalis
- diuretics
- vasodilators
- beta blockers
- angiotensin converting enzyme inhibitors (ACE inhibitors)
- angiotensin receptor blockers

Digitalis helps the heart muscle to have stronger pumping action. **Diuretics** help eliminate excess salt and water from the kidneys by making patients urinate more often. This helps reduce the swelling caused by fluid buildup in the tissues. **Vasodilators**, **beta blockers**, and ACE inhibitors lower blood pressure and expand the blood vessels so blood can move more easily through them. This action makes it easier for the heart to pump blood through the vessels.

Patients may also be given anticoagulant medications to prevent clots from forming due to pooling of blood in the heart chambers. Medicines to prevent abnormal heart rhythms (arrhythmias) may be given, but some of these drugs can also reduce the force of heart contractions. Automatic implantable cardioverter defibrillators (AICDs) can treat life-threatening arrhythmias, which are relatively common in severe cardiomyopathy.

Certain lifestyle changes may help reduce the workload on the heart and relieve symptoms. Some patients may need to change their diet, stop drinking alcohol, begin a physician-supervised **exercise** program, and/or stop **smoking**.

Severe congestive cardiomyopathy usually causes heart failure. When the heart muscle is damaged so severely that medicines cannot help, a heart transplant may be the only remaining treatment to be considered.

Prognosis

The outlook for a patient with congestive cardiomyopathy depends on the severity of the disease and the person's health. Generally, congestive cardiomyopathy worsens over time and the prognosis is not good. About 50% of patients with congestive cardiomyopathy live for five years after the diagnosis. Twenty-five percent of patients are alive 10 years after diagnosis. Women with congestive cardiomyopathy live twice as long as men with the disease. Many of the deaths are caused by sudden abnormal heart rhythms.

WWW.BOOKBAZ.IR

KEY TERMS

Angiotensin-converting enzyme (ACE) inhibitor—A drug that relaxes blood vessel walls and lowers blood pressure.

Atherosclerosis—Buildup of a fatty substance called a plaque inside blood vessels.

Cardiac catheterization—A diagnostic test for evaluating heart disease; a catheter is inserted into an artery and passed into the heart.

Cardiomyopathy—Disease of the heart muscle.

Congestive cardiomyopathy—Also called dilated cardiomyopathy; cardiomyopathy in which the walls of the heart chambers stretch, enlarging the heart ventricles so they can hold a greater volume of blood than normal.

Coxsackievirus B—A type of virus in the group Enterovirus that causes an infection similar to polio, but without paralysis.

Digitalis—A drug that helps the heart muscle to have stronger pumping action.

Dilated cardiomyopathy—Also called congestive cardiomyopathy; cardiomyopathy in which the walls of the heart chambers stretch, enlarging the heart ventricles so they can hold a greater volume of blood than normal.

Diuretic—A type of drug that helps the kidneys eliminate excess salt and water.

Edema—Swelling caused by fluid buildup in tissues.

Granulomatous myocarditis—Also called giant cell myocarditis, this noninfectious inflammation of the heart causes large areas of tissue death in the heart muscle, ventricular enlargement, and clots inside the heart chambers.

Idiopathic cardiomyopathy—Cardiomyopathy without a known cause.

Sarcoidosis—A chronic disease that causes formation of abnormal areas containing inflammatory cells, called granulomas, in any organ or tissue; in the heart, large areas of the heart muscle can be involved, causing cardiomyopathy.

Vasodilator—Any drug that relaxes blood vessel walls.

Ventricle—One of the two lower chambers of the heart.

Wegener's granulomatosis—A disease usually affecting males that causes the infiltration of inflammatory cells and tissue death in the lungs, kidneys, blood vessels, heart, and other tissues.

Prevention

Because idiopathic congestive cardiomyopathy does not have a known cause, there is no sure way to prevent it. The best way to prevent congestive cardiomyopathy is to avoid known causes such as drinking excess alcohol or taking toxic drugs. Eating a nutritious diet and getting regular exercise to improve overall fitness also can help the heart to stay healthy.

Congestive cardiomyopathy may also be prevented by identifying and treating any conditions that might damage the heart muscle. These include high blood pressure and coronary artery disease. Regular blood pressure checks and obtaining immediate medical care for hypertension and symptoms of coronary artery disease, such as chest **pain**, are important to keep the heart functioning properly.

Finally, diagnosing and treating congestive cardiomyopathy before the heart becomes severely damaged may improve the outlook.

Congestive heart failure

Definition

Congestive **heart failure** (CHF), sometimes simply known as heart failure, is a chronic, progressive condition in which the heart gradually becomes unable to pump enough blood to meet the nutritional and oxygen needs of the organs and tissues within the body. The term comes from the action of blood backing up into the liver, abdomen, lungs, and lower extremities, or congesting into these areas. CHF does not mean the heart fails, only that it has become weaker. Conditions that can leave the heart in poor condition include **coronary artery disease** (narrowed arteries in the heart) and high blood pressure (**hypertension**). In addition, CHF can result in the failure of other organs and eventually death. CHF is the leading cause of hospitalizations of people over the age of 65 years.

Description

The heart is a muscle containing four compartments or chambers that separate oxygen-poor blood from oxygen-rich blood. The atria are the top chambers. They receive blood from the body. The ventricles are the bottom chambers. They pump blood out to the body. Oxygen-poor blood enters the right atrium and then moves through a valve to the right ventricle. It is then pumped out of the right ventricle to the lungs where it picks up oxygen. The oxygen-rich blood returns to the left atrium of the heart, flows through a valve to the left ventricle, and is then pumped out to the body. This sequence occurs with every heartbeat. The timing of the contraction of each chamber of the heart must be exactly coordinated in order for each chamber to empty efficiently and completely.

Heart failure happens when a disease affects the heart's ability to deliver enough blood to the body's tissues. In this failure, the heart moves blood at a lower rate than normal, which causes pressure in the heart to increase. As a consequence, the heart fails to pump enough blood, which contains needed oxygen and nutrients, to meet the needs of other organs in the body.

Often, a person with heart failure may have a buildup of fluid in the tissues, called **edema**. Where edema occurs in the body depends on the part of the heart that is affected by heart failure. Heart failure caused by abnormality of the lower left chamber of the heart (left ventricle) means that the left ventricle cannot pump blood out to the body as fast as it returns from the lungs. Because blood cannot get back to the heart, it begins to back up in the blood vessels of the lungs. Some of the fluid in the blood is forced into the breathing space of the lungs, causing **pulmonary edema**. A person with pulmonary edema has **shortness of breath**, which may be acute, severe, and life threatening. A person with congestive heart failure feels tired because not enough blood circulates to supply the body's tissues with the oxygen and nutrients they need. Abnormalities of the heart structure and rhythm also can be responsible for left ventricular congestive heart failure.

The failure of the heart to pump adequately occurs for one of two reasons. In systolic heart failure (systole is the period when the heart contracts), disease weakens the wall of the ventricles, so that they pump less forcefully. In response, the heart muscle stretches to create larger chambers in the ventricles. This compensates for the heart's reduced pumping ability, but over time, the heart wall thickens, the chambers narrow, and the heart pumps out less and less blood. The volume of blood pumped out of the ventricle is called the ejection fraction (EF). In a healthy heart, the EF is greater than 50% (usually 55–70%), whereas in people with CHF, it is less than 50% and can be as low as 30%. Systolic heart failure is the most common kind of CHF.

In diastolic heart failure (diastole is the period when the heart relaxes and refills with blood), the

WWW.BOOKBAZ.IR

heart is not weakened, but it becomes stiff. After each contraction, it does not relax enough to fill completely. The EF is normal (over 50%), but with less blood in the ventricle, the absolute amount of blood pumped is decreased. Diastolic heart failure is most common among people over the age of 75 years.

When the left side of the heart begins to fail, fluids collect in the lungs causing lung congestion (pulmonary edema) and difficulty breathing. In right-sided heart failure, the lower right chamber of the heart (right ventricle) cannot pump blood to the lungs as fast as it returns from the body through the veins. Blood then engorges the right side of the heart and the veins. Fluid backed up in the veins is forced out into the tissues, causing swelling, usually in the feet and legs. Congestive heart failure of the right ventricle often is caused by abnormalities of the heart valves and lung disorders.

When the heart cannot pump enough blood, it tries to make up for this by becoming larger. By becoming enlarged (hypertrophic) the ventricle can contract more strongly and pump more blood. When this happens, the heart chamber becomes larger and the muscle in the heart wall becomes thicker. The heart also compensates by pumping more often to improve blood output and circulation. The kidneys try to compensate for a failing heart by retaining more salt and water to increase the volume of blood. This extra fluid also can cause edema. Eventually, as the condition worsens over time these measures are not enough to keep the heart pumping enough blood needed by the body. Kidneys often weaken under these circumstances, further aggravating the situation and making therapy more difficult.

CHF is often complicated by other health problems such as atherosclerotic **heart disease** (ASHD), cardiomyopathies, coronary artery disease, diabetes, high blood pressure (hypertension), **alcoholism**, **emphysema**, **chronic obstructive pulmonary disease** (COPD), heart rhythm abnormalities, **myocarditis**, and renal (kidney) disease.

Demographics

According to the U.S. Centers for Disease Control and Prevention (CDC), about 5.1 million Americans had CHF (as of 2014), with about 670,000 new cases diagnosed each year. In 2009, approximately one in nine deaths included heart failure as a contributing cause. Most people with CHF are elderly. Those who develop CHF die on average within five years of their diagnosis. Only 1% of people under age 50 years are diagnosed with CHF, but it is found in about 5% of people over age 75 and 25% of people over age 80. Men from the ages of 40 to 75 are more likely to have CHF than are women, but after age 75, the percentage of men and women with CHF is about equal.

Race is a factor in one's risk from death related to CHF. African Americans are 1.5 times more likely to die of CHF than are white Americans. In addition, the number of people with CHF is expected to increase as the American population ages. With this increase is an increase in health costs related to heart failure. In 2011, the CDC estimated that the United States spends about $32 billion annually for health care related to heart failure. This amount includes the cost of medicines to treat CHF, along with the expenses related to healthcare services and the days missed from work due to heart failure.

Causes and symptoms

Most often, the causes of heart failure are due to the adverse effects of other medical conditions that damage or weaken the heart. The end cause of CHF is failure of the heart to pump enough blood, but many other conditions can contribute to or accelerate this failure. These include heart damage caused by disease and lifestyle. Common conditions contributing to CHF that make the heart work harder and can increase the risk of CHF include:

- disease of the arteries that causes decreased blood flow to the heart muscle (coronary artery disease, abbreviated CAD)
- prolonged, uncontrolled high blood pressure (hypertension)
- previous heart attack (myocardial infarction)
- heart valve abnormalities and disease
- prolonged heart arrhythmias
- thyroid disease
- infection of the heart muscle or surrounding tissue (endocarditis)
- damage to the heart muscle from alcohol, cocaine, or other substance abuse
- congenital (present at birth) heart defects
- obesity
- kidney disease
- diabetes, particularly poorly controlled diabetes
- smoking of tobacco products

Symptoms of CHF usually begin gradually and initially may go unnoticed. The exception is after a **heart attack**, when moderate-to-severe symptoms can develop rather rapidly. CHF symptoms are similar to those caused by many diseases, making diagnosis

more difficult. Often symptoms are complicated by other diseases in the elderly such as diabetes, emphysema or other lung diseases, and reduced kidney function.

The first symptom usually noticed is shortness of breath (dyspnea) when performing normal activities such as walking, cleaning the house, or doing easy yard work, along with general **fatigue**. Symptoms then progress to include:

- shortness of breath and difficulty breathing even at rest
- fluid and water retention and swelling (edema) of the ankles, feet, and legs (less blood to the kidneys can cause fluid and water build up, which can result in an swollen abdomen and swelling in the ankles, feet, legs, and abdomen)
- weakness and extreme fatigue (less blood in the major organs of the body and muscles can lead to tiredness and weakness)
- dizziness from not enough oxygen reaching the brain (less blood to the brain can cause dizziness and confusion)
- persistent cough or wheezing, often including whitish-pink phlegm that contains a trace of blood
- increased need to urinate throughout the night
- lack of appetite
- decreased mental alertness and difficulty concentrating
- fast and/or irregular heartbeat (with less blood going to the heart and other parts of the body, the heart speeds up to compensate, which leads to a rapid or irregular heartbeat)
- congested lungs

Diagnosis

Diagnosis begins with a doctor performing a complete **physical examination**, along with compiling the patient's health, medication, and lifestyle history. A person's symptoms can provide important clues to the presence of heart failure. Shortness of breath (while engaging in activities) and episodes of shortness of breath that wake a person from sleep are classic symptoms of heart failure. During the physical examination, the physician listens to the heart and lungs with a stethoscope for telltale signs of heart failure. Irregular heart sounds, gallops, a rapid heart rate, and murmurs of the heart valves may be heard. If there is fluid in the lungs, a crackling sound may be heard. Rapid breathing or other changes in breathing may also be present. Patients with heart failure also may have a rapid pulse.

By pressing on the abdomen, the physician can feel if the liver is enlarged. The skin of the fingers and toes may have a bluish tint and feel cool if not enough oxygen is reaching them.

The following tests are used to make a diagnosis of CHF:

- Chest x ray: noninvasive test that shows if fluid is building up in the lungs or if the heart is enlarged. Abnormalities of heart valves and other structures may also be seen on a chest x ray.
- Electrocardiogram (ECG or EKG): noninvasive test that helps detect abnormalities in heart rhythm and heart health by measuring the electrical activity of the heart. It can show if the heart chamber is enlarged and if there is damage to the heart muscle from blocked arteries.
- Ultrasound: noninvasive test that assesses the anatomy and function of the heart, including measurement of blood flow within the heart, contractions of the heart's chambers, and the ejection fraction (which is a measure of how well the heart is pumping blood).
- Blood tests: check for anemia (low iron), chemical (electrolyte) imbalances in the blood, kidney and thyroid function, and cholesterol levels; specifically, a b-type natriuretic peptide (BNP) blood test is performed to analyze BNP, a substance secreted from the heart in response to changes in blood pressure when heart failure first develops or later worsens. Some of these blood tests include a complete blood count (CBC), electrolytes, glucose, blood urea nitrogen (BUN), and creatinine.
- Kidney function tests: help pinpoint the cause of fluid retention.
- B-type natriuetic peptide (BNP) test: measures the hormone BNP, which is produced in greater quantity when the heart begins to fail.
- Echocardiogram: noninvasive imaging test that uses sound waves to produce a picture of the heart in motion as it beats. It is extremely helpful in showing heart and valve damage. Such pictures can also show if the heart wall or chambers are enlarged and if there are any abnormalities of the heart valves; can be used to find out how much blood the heart is pumping; and determines the amount of blood in the ventricle (ventricular volume).
- Multiple-gated acquisition (MUGA) scan: imaging test that uses radioactive dye injected in the veins to produce a picture of blood circulation in the heart.
- Stress test: an electrocardiogram done while exercising or, for people who cannot exercise, while the heart is stimulated by medication.

WWW.BOOKBAZ.IR

- Cardiac computerized tomography (CT) and magnetic resonance imaging (MRI): help to diagnosis the cause of heart failure by producing images of the heart.
- Coronary catheterization (angiogram): identifies narrowing of the arteries in and around the heart and helps to determine the strength of the left ventricle (the main pumping chamber of the heart) and the valves of the heart.
- Myocardial biopsy: small pieces of the heart muscle removed for laboratory analysis of what disease(s) are affecting the heart.
- Radionuclide ventriculography: measures the ejection fraction (EF) by imaging with very low doses of an injected radioactive substance as it travels through the heart; EF is used to measure the efficiency of the heart's pumping mechanism (the amount of blood the ventricle pumps each time it beats).

The degree or stage of CHF can be designated using several different scales. The two most common are the New York Heart Association (NYHA) scale that uses a numbered system (I-IV) that classifies CHF by symptoms and functional limits and the American College of Cardiology (ACC) and the American Heart Association (AHA) scale that use a letter system (A-D) to designate risk factors for CHF. These two scales are often used in unison by doctors developing the best treatment options for their patients.

The NYHA scale describes the following: Class I heart failure, no symptoms; Class II, able to perform everyday activities without difficulty but becomes winded or fatigued under exertion; Class III, having trouble completing everyday activities, and Class IV, shortness of breath even at rest. The ACC/AHA guidelines describe the least serious stage as Stage A, in which a person has several risk factors for heart failure but no symptoms of heart failure; whereas Stage D is described as a person with end-stage heart failure requiring hospice care. Stages B and C are described as intermediate classifications.

Treatment

Treatment does not cure CHF, but it can slow its progression, extend life, and to some degree lessen symptoms. Treatment of CHF falls into three categories: lifestyle changes, drug therapy, and surgery.

Lifestyle changes

Self-care lifestyle changes that help slow the progression of CHF include:

- reducing sodium (salt) in the diet
- eating a heart-healthy diet high in fresh fruits, fresh vegetables and whole grains, and low in fats, especially saturated (animal) fats
- controlling calorie intake and losing weight if overweight or obese
- quitting the use of tobacco products
- avoiding alcohol
- exercising moderately (e.g., walking) or joining a cardiac rehabilitation program
- treating any other health problems or underlying diseases
- elevating the feet when sitting to discourage fluid accumulation
- taking all medicines as prescribed
- weighing daily to check for sudden spikes in fluid retention
- scheduling regular examinations with a healthcare provider

Drug therapy

Many drugs are available to treat CHF. People with CHF often need more than one drug to control or slow symptoms. The development of new drugs to treat CHF is an area of active research because of the **aging** population of many developed countries.

Common drugs used to treat CHF include:

- Angiotensin converting enzyme (ACE) inhibitors: these drugs block the formation of angiotensin, a hormone that may adversely affect the heart. ACE inhibitors include captopril (Capoten), enalapril (Vasotec), lisinopril (Zestril, Prinvil), benazepril (Lotensin), and ramipril (Altace).
- Angiotensin II receptor blockers: these drugs also block the formation of angiotensin using a different mechanism than ACE inhibitors. They are generally less effective than ACE inhibitors and are given to people who do not tolerate ACE-inhibiting drugs. Examples include losartan (Cozzar), candesartan (Atacand), telmisartan (Micardis), valsartan (Diovan), and irbesartan (Avapro).
- Beta-blockers: these drugs block the effect of stimulant hormones such as epinephrine (adrenalin) and norepinephrine (noradrenaline). Carvedilol (Coreg) is approved by the U.S. Food and Drug Administration (FDA) for this use, although other beta-blockers are sometimes prescribed as off-label use. Others include metoprolol (Lopressor and bisoprolol (Zebeta).
- Digoxin (Lanoxin): One of the oldest treatments for CHF and also called digitalis, this drug is a natural compound found in the plant foxglove *Digitalis*

purpurea. It helps to increase the strength of the contractions found within the heart muscle.

- Diuretics: these drugs help rid the body of excess fluid by increasing urine production. Common diuretics include furosemide (Lasix), bumetanide (Bumex), torsemide (Demadex), metolazone (Zaroxolyn), spironolactone (Aldactone), and hydrochlorothiazide.
- Hydralazine (Apresoline): this drug has been shown to benefit African Americans but confers no benefit on people of other races.
- Aldosterone antagonists: including such drugs as spironolactone (Aldactone) and eplerenone (Inspra), these drugs remove some scarring from the heart and help to improve systolic heart failure.
- Inotropes: used for the severest of cases, these medications are taken intravenously to improve heart function and control blood pressure.

There are also drugs that a CHF patient should avoid because they worsen CHF or interfere with treatment drugs. These include **nonsteroidal anti-inflammatory drugs** (e.g., Aleve, Motrin), **decongestants** (e.g., Sudafed), **calcium channel blockers**, anti-arrhythmia drugs, growth hormones, **antacids** that contain **sodium**, and salt substitutes. Patients with CHF should not take any herbal remedy or dietary supplement without first consulting their healthcare provider. In addition, some drugs used to treat underlying diseases may need to be adjusted because they interfere with drug therapy for CHF.

Surgery

Surgery does not cure CHF although it can prolong life and improve the quality of life. Surgery can be performed to remedy a defect or condition that is contributing to CHF. Examples are **heart valve repair** and coronary artery surgery to improve blood flow in the heart. Complete heart **transplant surgery** to treat CHF is severely limited by the number of donor hearts available. It is normally done only on younger patients such as those with congenital heart defects.

Prognosis

Most patients with mild or moderate heart failure can be successfully treated with dietary and **exercise** programs and the correct type of medications. CHF is a progressive condition; it can be slowed but not cured. Between 30% and 40% of people with CHF are hospitalized every year, and it is a leading cause of death among the elderly. About half the deaths among people with CHF are from progressive heart failure, and the other half are sudden deaths, most often due to severe heart **arrhythmias**. The average survival time from diagnosis is 3.2 years in men and 5.4 years in women. Risk of death after diagnosis is over 20% at one year. Those patients with NYHA stage IV failure (the last stage) have a mortality rate of up to 50% Nevertheless, survival times vary widely depending on individuals' general health, the treatment they receive, and how well they maintain their lifestyle and drug regimens.

Nutrition/Dietetic concerns

Sodium (Na) found in salt promotes water retention in the body. People with CHF need to severely restrict their intake of salt. Salt is found in many processed foods, so that even a no-salt-added diet provides from 4,000 mg to 6,000 mg of salt daily. People with CHF need to limit their salt intake to no more than 2,000 mg of salt per day. Doing so requires careful reading of food labels (sodium content is listed in the **nutrition** panel) and for many, a major change in the foods they eat. Fluid intake is also a concern for people with CHF and is often limited to no more than 8 c. (2 L) of fluids daily from all sources combined.

Exercise therapy

Lifestyle changes can help those with CHF. Studies have found that limited, supervised exercise can benefit people with CHF. An individualized **cardiac rehabilitation** program can provide an appropriate type and level of exercise.

Caregiver concerns

Staying on the prescribed drug regimen and making positive lifestyle changes is important in slowing the progression of CHF and improving patient symptoms. People with CHF often take multiple drugs several times a day. Caregivers can help their charges achieve maximum benefits from their medications by familiarizing themselves with the required drug regimen and organizing a system that makes it easy for them and their charges to remember to take these medications. A medicine box with separate compartments for several times of day and all the days of the week is helpful. Another part of caring for a person with CHF is organizing a daily weighing in order to determine if fluid retention has suddenly increased. Finally, the care giver must understand and conform to the dietary needs of the person with CHF, with special care paid to the amount of salt in the diet.

Prevention

Congestive heart failure cannot be prevented. However, prevention activities are the same as the

WWW.BOOKBAZ.IR

lifestyle changes used to slow the progression of CHF, namely eating a heart-healthy diet, exercising regularly, maintaining a healthy weight, avoiding tobacco products, and limiting alcohol consumption. Treating or controlling any underlying diseases such as diabetes and high blood pressure also are important preventative steps.

The WebMD article "How Can I Prevent Heart Failure from Worsening?" lists ways to lower one's risk of CHF:

- Maintain a low blood pressure: a controlled, low blood pressure level allows the heart to pump more effectively without overdue stress.
- Maintain proper cholesterol levels.
- Control diabetes.
- Monitor symptoms: changes in fluid and water retention in the body should be checked daily; an increase of 3 lb. (1.4 kg) in a day or 5 lb. (2.3 kg) in a week should be reported to a medical professional.
- Maintain a healthy intake and output of fluids in the body: the more fluids taken in daily and the fewer times fluids are removed from the body, the more difficult it is for the heart to function.
- Limit the amount of salt intake: low salt in one's diet helps to minimize fluid retention, lower blood pressure, and helps to prevent swelling in the extremities and allows the lungs to work better.
- Monitor body weight on a daily basis, and lose weight if overweight or excessively overweight (obese).
- Take medications as directed: taking medicine in the proper dosage and at the prescribed times helps to improve the ability of the heart to function properly.
- Schedule regular appointments with the family doctor: proper treatment and care by medical professionals helps individuals stay as healthy as possible and to minimize the problems associated with congestive heart failure.
- Stop using tobacco products in all forms.
- Exercise regularly (on most days of the week).
- Limit the amount (no more than one drink for women and two drinks for men daily) or do not drink alcohol.

Several types of medications should be avoided when congestive heart failure is present. These are:

- nonsteroidal anti-inflammatory drugs (NSAIDs) such as naproxen (such as Aleve) and ibuprofen (Motrin); instead use acetaminophen (Tylenol)
- certain antiarrhythmic agents (ask a medical professional for those that should be avoided)
- some diabetes medicines such as rosiglitazone (Avandia) and pioglitazone (Actos)
- most calcium channel blockers (if systolic heart failure is present)
- some nutritional supplements (especially those that contain salt or salt substitutes)
- medicines involving growth hormone therapies
- antacids that contain salt (sodium chloride)
- decongestants such as those that contain the active ingredient pseudoephedrine as in the branded product Sudafed

KEY TERMS

Arrhythmia—An abnormal heart rhythm.

Atrium (plural Atria)—The right or left upper chamber of the heart.

Cardiac rehabilitation—A structured program of education and activity offered by hospitals and other organizations.

Coronary artery disease—Also called atherosclerosis, a build-up of fatty matter and debris in the coronary artery wall that causes narrowing of the artery.

Echocardiogram—A noninvasive imaging procedure used to create a picture of the heart's movement, valves, and chambers.

Electrocardiogram (ECG)—A noninvasive test that records the electrical activity of the heart and is useful is assessing general heart health.

Off-label use—Drugs in the United States approved by the Food and Drug Administration (FDA) for specific uses based on the results of clinical trials and prescribed legally by physicians for other off-label uses. It is not legal for pharmaceutical companies to advertise drugs for off-label uses.

Stress test—A test that involves an electrocardiogram during rest and exercise to determine how the heart responds to stress.

Ventricle—The lower pumping chambers of the heart. There are two ventricles, right and left. The right ventricle pumps oxygen-poor blood to the lungs to be reoxygenated. The left ventricle pumps oxygen-rich blood to the body.

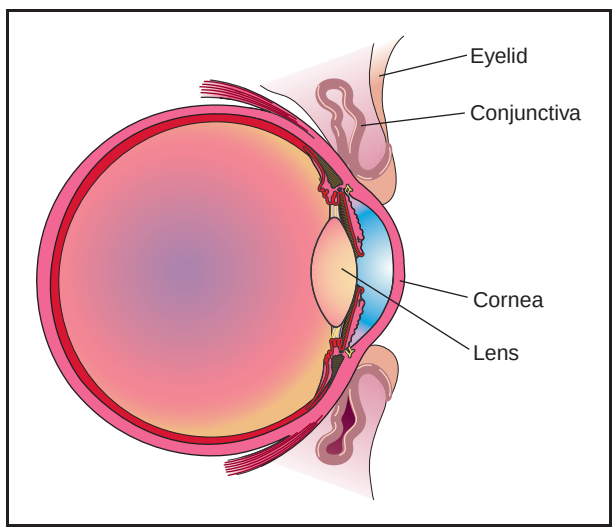
Conjunctivitis

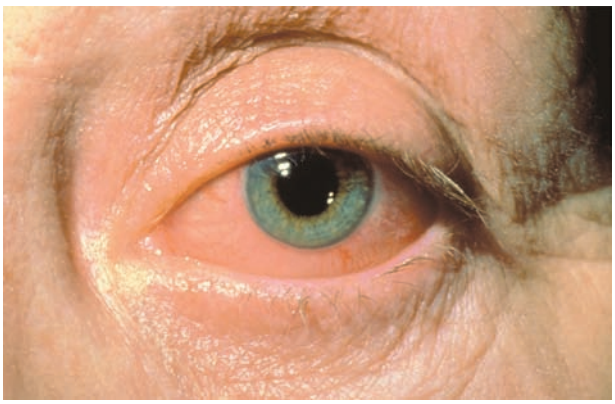
Definition

Conjuctivitis is an inflammation or redness of the lining of the white part of the eye and the underside of the eyelid (conjunctiva) that can be caused by bacterial or viral infection, allergic reaction, chemical irritants, or physical agents like infrared or ultraviolet light. Viral conjunctivitis is sometimes called pink eye or red eye because the tissues lining the affected eye often develop a bright pink color as well as being swollen.



Conjunctivitis is the inflammation of the conjunctiva, a thin, delicate membrane that covers the eyeball and lines the eyelid. It may be caused by a viral infection, such as a cold or acute respiratory infection, or by such diseases as measles, herpes simplex, or herpes zoster. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

WWW.BOOKBAZ.IR



This person has severe conjunctivitis, most likely caused by an allergic reaction. *(Custom Medical Stock Photo, Inc.)*

Conjunctivitis in the newborn, sometimes called neonatal conjunctivitis or ophthalmia neonatorum, is sometimes discussed as a distinctive type of conjunctivitis because it is caused by an infection passed from the mother to the child during delivery. If untreated, it can cause blindness.

Demographics

Conjunctivitis is a common eye disorder in all age groups worldwide, in part because it has so many possible causes. It is one of the most common non-traumatic eye disorders that are seen in hospital emergency rooms, accounting for about 1% of all ER visits in North America. The conjunctivae of the human eye are continually exposed to microorganisms and environmental agents that can cause infections or allergic reactions. Conjunctivitis can be acute or chronic depending upon how long the condition lasts, the severity of symptoms, and the type of organism or agent involved. It can also affect one or both eyes and, if caused by infection, can be very easily transmitted to others during close physical contact, particularly among children in a daycare center.

About 15% of people in the United States will have at least one episode of allergic conjunctivitis over a lifetime; rates in other countries are thought to be similar.

Viral conjunctivitis is most likely to affect people in the United States and Canada in the late fall and early spring. This type of conjunctivitis is equally common in males and females, and in members of all races and ethnic groups.

Between 1% and 2% of babies born in the United States are diagnosed with infectious neonatal conjunctivitis. The most common cause of this type of conjunctivitis is *Chlamydia trachomatis*, a parasite that lives within the tissues of an infected mother's cervix. The second most common cause is *Neisseria gonorrhoeae*, the gonococcus or bacterium that causes **gonorrhea**. Conjunctivitis caused by *N. gonorrhoeae* is potentially the most dangerous to newborns.

Description

The conjunctiva (plural, conjunctivae) in humans is a loose sheet of connective tissue that covers the eyeball and doubles back to form the inner lining of the eyelid. Some of the smaller tear glands that keep the eye lubricated are located within the conjunctivae. Because the conjunctivae are moist mucous membranes, **infectious disease** organisms can easily cling to them until they multiply and overwhelm the eye's defense mechanisms, producing redness, irritation, and sand-in-the-eye or itchy sensations, discharge, and sometimes photophobia (extreme sensitivity to light).

Conjunctivitis in newborns is typically characterized by swelling of the eyelid, tenderness of the eyeball, and a discharge. Depending on the organism causing the infection, the discharge may be either watery mucus or a liquid form of pus. In some cases the discharge may be thick enough to form a yellowish crust on the baby's eyelids.

Risk factors

The most common risk factors for conjunctivitis include:

- exposure to other children or family members with conjunctivitis
- exposure to allergens, most commonly grass or tree pollen
- recent history of an upper respiratory infection; this is a risk factor for viral conjunctivitis
- weakened immune system
- personal history of asthma or eczema; this is a risk factor for allergic conjunctivitis
- frequent use of eye cosmetics
- wearing contact lenses, particularly the extended-wear type

Causes and symptoms

The symptoms of conjunctivitis vary somewhat according to its cause. Conjunctivitis may be caused by a viral infection, such as a cold, acute respiratory infection, or disease such as **measles**, herpes simplex, or herpes zoster. Symptoms include mild to severe

KEY TERMS

Adenovirus—A virus that affects the upper respiratory tract.

Chlamydia—The most common bacterial sexually transmitted disease in the United States that often accompanies gonorrhea and is known for its lack of evident symptoms in the majority of women.

Gonococcus (plural, gonococci)—The bacterium *Neisseria gonorrheae* that causes gonorrhea, a sexually transmitted infection of the genitals and urinary tract. Gonococci may occasionally affect the eye, causing blindness if not treated.

Herpes simplex virus—A virus that can cause fever and blistering on the skin, mucous membranes, or genitalia.

Herpes zoster virus—Acute inflammatory virus that attacks the nerve cells on the root of each spinal nerve with skin eruptions along a sensory nerve ending.

Neonatal—Referring to the period shortly after birth.

Ophthalmia neonatorum—The medical term for conjunctivitis in newborns.

Photophobia—Extreme sensitivity to light.

Staphylococcus—A bacterial organism, looking much like a cluster of grapes, that can infect various body systems.

Streptococcus—An organism that causes infections of either the upper respiratory or gastrointestinal tract.

discomfort in one or both eyes, redness, swelling of the eyelids, and watery, yellow or green discharge. Symptoms may last anywhere from several days to two weeks. Infection with an adenovirus, may also cause a significant amount of pus-like discharge and a scratchy, foreign body-type of sensation in the eye. This may also be accompanied by swelling and tenderness of the lymph nodes near the ear.

Bacterial conjunctivitis can occur in adults and children and is caused by such organisms as *Staphylococcus*, *Streptococcus*, and *Hemophilus*. Symptoms of bacterial conjunctivitis include a pus-like discharge and crusty eyelids after awakening. Redness of the conjunctiva can be mild to severe and may be accompanied by swelling. Persons with symptoms of conjunctivitis who are sexually active may possibly be infected with the bacteria that cause either gonorrhea or chlamydia. There may be large amounts of pus-like discharge, and symptoms may include intolerance to light (photophobia), watery mucous discharge, and tenderness in the lymph nodes near the ear that may persist for up to three months.

Conjunctivitis may also be caused by such environmental hazards as wind, smoke, dust, and allergic reactions caused by pollen, dust, or grass. Symptoms range from **itching** and redness to a mucous discharge. Persons who wear **contact lenses** may develop allergic conjunctivitis caused by the various eye solutions and foreign proteins contained in them.

Other less common causes of conjunctivitis include exposure to sun lamps or the electrical arcs used during welding, and problems with inadequate drainage of the tear ducts.

In a few cases, children can get conjunctivitis from accidental exposure to chemical irritants, such as strong detergents.

Diagnosis

The most important aspect of diagnosing conjunctivitis is to separate the cases with benign causes (the great majority) from the small group of cases with complications or more serious causes (particularly chemical injury). Conjunctivitis can be diagnosed by a primary care doctor, pediatrician, emergency room physician, or ophthalmologist (specialist in eye disorders); patients with severe inflammation or conjunctivitis caused by getting a strong chemical in the eye will usually be referred to an ophthalmologist.

Examination

An accurate diagnosis of conjunctivitis centers on taking a patient history to learn when symptoms began, the specific symptoms experienced, and other predisposing factors, such as upper respiratory complaints, **allergies**, sexually transmitted diseases, herpes simplex infections, and exposure to schoolmates or other persons with pink eye. It may be helpful to learn whether an aspect of an individual's occupation may be the cause.

After taking the history, the doctor will examine the patient's eye with a light to check the eyelid and conjunctiva for swelling, change in color, discharge, and any other abnormalities. The doctor may also collect a small sample of the discharge for culture if bacterial conjunctivitis is suspected.

WWW.BOOKBAZ.IR

Tests

Laboratory tests are usually not indicated in adults unless initial treatment fails (usually within 24–36 hours) or an infection with gonorrhea or chlamydia is suspected. In such cases, the discharge may be cultured and Gram-stained to determine the organism responsible for the condition. Cultures and smears are relatively painless procedures.

Cultures are usually taken when the patient is a newborn, has a weakened immune system, or is thought to have conjunctivitis caused by *N. gonorrhoeae*.

Treatment

Traditional

The treatment of conjunctivitis depends on what caused the condition. In all cases, warm compresses applied to the affected eye several times a day may help to reduce discomfort. Some treatment choices will be based on patient preference, convenience of use, and cost to the patient.

Conjunctivitis due to a viral infection, particularly those due to adenoviruses, are usually treated by applying warm compresses to the eye(s) and applying topical antibiotic ointments to prevent secondary bacterial infections. Viral conjunctivitis caused by herpes simplex should be referred to an ophthalmologist. Topical **steroids** are commonly prescribed in combination with antiviral therapy.

Allergic conjunctivitis can be treated by removing the allergic substance from a person's environment, if possible; by applying cool compresses to the eye; and by administering eye drops four to six times daily for four days. Oral **antihistamines** may help to relieve itchy eyes. However, many of these drugs also dry the eyes. Therefore, many physicians suggest a combination of antihistamines and lubricating drops or the use of nasal corticosteroid sprays to help relieve allergic conjunctivitis, particularly when it is combined with nasal symptoms. Non steroidal anti-inflammatory drugs (NSAIDs) can be used to reduce the itching associated with allergic conjunctivitis as well as to reduce inflammation.

Drugs

Medications of various types are used to treat conjunctivitis caused by bacteria. In cases of bacterial conjunctivitis, a physician may prescribe an antibiotic eye ointment or eye drops containing **sodium** sulfacetamide (Sulamyd) to be applied daily for 7 to 14 days. If, after 72 hours, the condition does not improve, a physician or primary care provider should be notified because the bacteria involved may be resistant to the antibiotic used or the cause may not be bacterial. The U.S. Food and Drug Administration (FDA) approved a new drug, besifloxacin (Besivance), for the treatment of bacterial conjunctivitis. The new drug is given as eye drops, can be safely used in patients older than 12 months, and has fewer side effects than other antibacterial eye drops.

For cases of conjunctivitis caused by *N. gonorrhoeae*, a physician may prescribe an intramuscular injection of ceftriaxone (Rocephin) and a topical antibiotic ointment containing erythromycin or bactracin to be applied four times daily for two to three weeks. Sexual partners should also be treated.

With accompanying chlamydia infection, a topical antibiotic ointment containing erythromycin (Ilotycin) may be prescribed to be applied one to two times daily. In addition, oral erythromycin or tetracycline therapy may be indicated for three to four weeks. Again, sexual partners should also be treated.

Conjunctivitis in the newborn is treated with a combination of eye drops or eye ointments containing erythromycin or tetracycline. Salt water drops may be used to wash away any sticky crust that has formed on the eyelids. Babies born to mothers with untreated gonorrhea may need intravenous or intramuscular injections of ceftriaxone, ciprofloxacin, or cefotaxime.

Alternatives

Conjunctivitis caused by gonococcal and chlamydial infection usually requires conventional medical treatment. With bacterial, viral, and allergic conjunctivitis, however, alternative options can be helpful. Internal immune enhancement with supplementation can aid in the resolution of bacterial and viral conjunctivitis. Removal of the allergic agent is an essential step in treating allergic conjunctivitis. As with any of the recommended treatments, however, if no improvement is seen within 48–72 hours, a physician should be consulted.

There are a number of acute homeopathic remedies designed to treat conjunctivitis. These include *Pulsatilla* (windflower, *Pulsatilla nigricans*), *Belladonna*, and eyebright (*Euphrasia officinalis*). Eye drops prepared with homeopathic remedies and/or herbs can be a good substitute for pharmaceutical eye drops. Eye washes can also be made. Herbal eyewashes made with eyebright (1 tsp. dried herb steeped in 1 pint of boiling water) or chamomile (*Matricaria recutita*; 2–3 tsp. in 1 pint of boiling water) may be helpful. Eyewashes should be strained and cooled before use, and close attention should be paid to make sure that any solution put into the eye is sterile.

Home remedies

Several simple home remedies may help relieve the discomfort associated with conjunctivitis. A boric acid eyewash can be used to clean and soothe the eyes. A warm compress applied to the eyes for 5–10 minutes three times a day can help relieve the discomfort of bacterial and viral conjunctivitis. A cool compress or cool, damp tea bags placed on the eyes can ease the discomfort of allergic conjunctivitis.

Prognosis

If treated properly, the prognosis for conjunctivitis in adults and older children is good. Conjunctivitis caused by an allergic reaction should clear up once the allergen is removed. Allergic conjunctivitis will likely recur if the individual again comes into contact with the particular allergen. Conjunctivitis caused by bacteria or a virus, if treated properly, is usually resolved in 10–14 days. If there is no relief of symptoms in 48–72 hours, or there is moderate to severe eye **pain**, changes in vision, or the conjunctivitis is suspected to be caused by herpes simplex, a physician should be notified immediately. If untreated or if treatment fails and is not corrected, conjunctivitis may cause **visual impairment** by spreading to other parts of the eye, such as the cornea.

Untreated conjunctivitis in newborns caused by sexually transmitted diseases can lead to blindness. A century ago, as many as 24% of American children enrolled in schools for the blind had lost their sight as a result of gonorrheal conjunctivitis.

Prevention

The American Academy of Ophthalmology recommends the following preventive measures to lower the risk of conjunctivitis:

- Wash hands frequently using antiseptic soap, and use single-use towels during the disease to prevent spreading the infection. People with viral conjunctivitis can spread the disease to others for as long as two weeks after symptoms appear.
- Avoid chemical irritants and known allergens; handle strong detergents, drain cleaners, ammonia, chlorine bleach, and other household chemicals with care.
- If in an area where welding occurs, using the proper protective eye wear and screens to prevent damaging the eyes.
- Use a clean tissue to remove discharge from eyes.
- If medication is prescribed, finish the course of antibiotics as directed to make sure that the infection is cleared up and does not recur.
- Avoid such contact as vigorous physical activities with other persons until symptoms resolve; in particular, stay away from swimming pools.
- Women who use mascara and other eye cosmetics should replace them frequently and not share them with others.
- Avoid sharing pillowcases and bath towels.
- Clean contact lenses carefully and properly.

Chlamydial or bacterial conjunctivitis of the newborn can be avoided by treating the mother for sexually transmitted diseases before delivery; by delivering the baby by **cesarean section**; and by placing an antibiotic ointment in the baby's eyes as soon as possible after delivery.

Constipation

Definition

Constipation, also called costiveness and dyschezia, is an acute or chronic condition in which it is difficult to produce a bowel movement or when bowel movements do occur they are infrequent and contain hard, dry, and small stools that are painful and/or difficult to pass. Although constipation is not usually a serious condition—almost everyone gets constipated from time to time—it can cause concern for those who are afflicted with it frequently or for long periods.

Description

Bowel habits vary, but in general an adult who has not had a bowel movement in three days or a child who has not had a bowel movement in four days is considered constipated. The longer a person goes without a bowel movement, the more likely is the stool to be more difficult to pass.

Constipation can be acute, meaning that it comes on suddenly and lasts only for a short time. By contrast, chronic constipation lasts for a long time. In most cases, constipation is acute and is not considered dangerous to the health of the individual. However, it always should be a concern to anyone who has constipation. The Mayo Clinic considers constipation to be when a person has two or more of the following for at least three months:

- bowel movements occur two times or less during any given week
- bowel movements cause straining in over 25% of the time
- stools are hard 25% or more of the time
- evacuation of stool is incomplete in one or more out of four times

Although constipation is rarely serious, it can lead to the following:

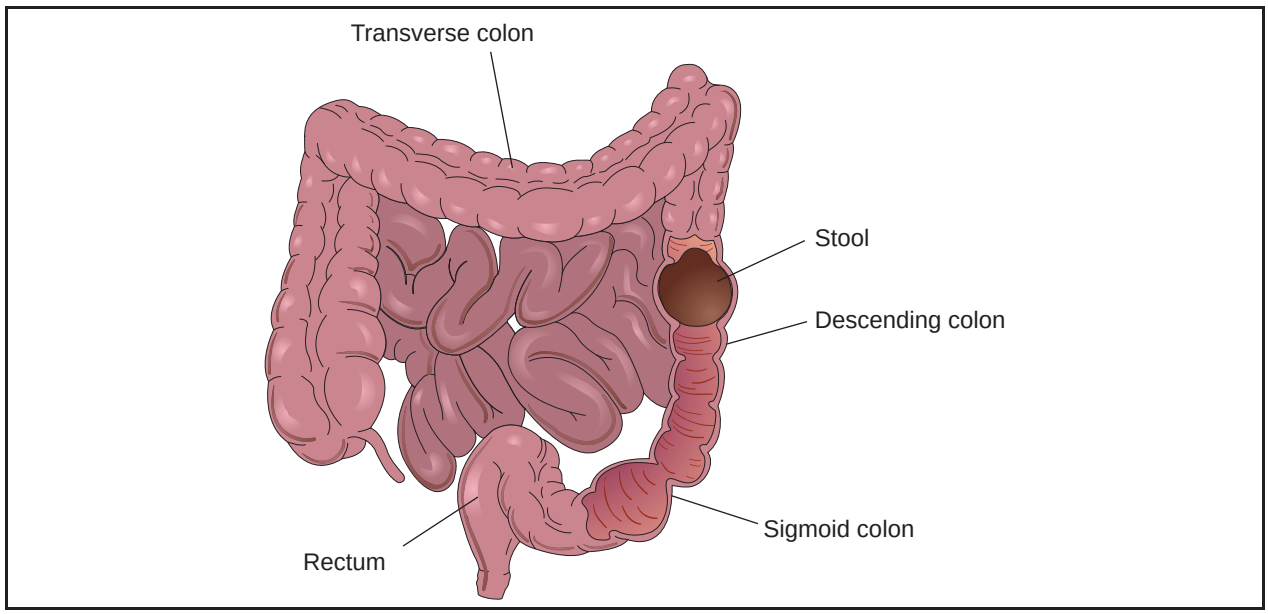
- bowel obstruction
- chronic constipation
- hemorrhoids (a mass of dilated veins in swollen tissue around the anus)
- hernia (a protrusion of an organ through a tear in the muscle wall)
- spastic colitis (irritable bowel syndrome, a condition characterized by alternating periods of diarrhea and constipation)
- laxative dependency

Severe constipation may occur in the form of obstipation (failure to pass stool or gas) and fecal impaction (which is a milder case of obstipation). Both can lead to life-threatening conditions if not treated promptly and effectively.

Chronic constipation may be a symptom of other diseases such as colorectal cancer, depression, diabetes, **diverticulosis** (small pouches in the muscles of the large intestine), **lead poisoning**, or Parkinson's disease.

In someone who is elderly or disabled, constipation may be a symptom of bowel impaction, a more serious condition in which feces are trapped in the lower part of the large intestine. A doctor should be called if an elderly or disabled person is constipated for a week or more or if a child seems to be constipated.

Further, a doctor should be notified whenever constipation occurs after starting a new prescription, vitamin or mineral supplement, or herbal remedy, or when constipation is accompanied by abdominal **pain**, blood in the stools, changes in bowel patterns, or **fever**.



Constipation is an acute or chronic condition in which bowel movements occur less often than usual or consist of hard, dry stools that are painful or difficult to pass. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Demographics

Constipation is one of the most common medical complaints in the United States. About 2% of Americans describe being constipated continuously or frequently, with women complaining of constipation more than men. Further, pregnant woman are more likely to complain of being constipated than are nonpregnant women. Age alone does not increase the frequency of constipation, but people 65 years of age or older, especially women, are more likely to experience constipation.

According to the National Digestive Diseases Information Clearinghouse (NDDIC), a part of the U.S. National Institutes of Health, people of lower socioeconomic classes and non-Caucasians report constipation more frequently than other Americans. Less frequent cases of constipation can occur in upwards to 30% of the population. The NDDIC states that constipation affects about 15% of the U.S. population in any given year. Internationally, the incidence of constipation varies, depending largely on dietary habits of people from a particular region or country.

Constipation can occur at any age and is more common among individuals who resist the urge to move their bowels at their body's signal. This often happens when children start school or enter daycare and feel shy about asking permission to use the bathroom. It also can happen to adults who are in jobs where they cannot take bathroom breaks whenever they choose.

Causes and symptoms

Constipation generally is caused by a nerve or muscular disorder in the function of the bowel. Structural bowel problems do occur but on a much less frequent basis. Constipation usually results from not getting enough **exercise**, not drinking enough water, or from a diet that does not include an adequate amount of fiber-rich foods such as dried beans, bran cereals, fruits, raw vegetables, rice, and whole-grain breads. It can also occur due to a disruption in a daily routine, such as during extended traveling, **stress**, and the consumption of large quantities of dairy products. The overuse of **laxatives** over a lengthy period of time can also cause constipation, as can the presence of **hemorrhoids**, which often causes one to resist having a bowel movement because it can be painful.

Other causes of constipation include anal fissure (a tear or crack in the lining of the anus), **chronic kidney failure**, colon or **rectal cancer**, depression, **hypercalcemia** (abnormally high levels of **calcium** in the blood), **hypothyroidism** (underactive thyroid gland), illness requiring complete bed rest, **eating disorders**, and **irritable bowel syndrome**. Neurological conditions such as **multiple sclerosis** and Parkinson's disease can also cause the condition to occur.

WWW.BOOKBAZ.IR

Constipation also can be a side effect of various medications, including the following:

- aluminum salts in antacids
- antihistamines
- antipsychotic drugs
- aspirin
- belladonna (*Atopa belladonna,* source of atropine, a medication used to relieve spasms and dilate the pupils of the eye)
- beta blockers (medications used to stabilize irregular heartbeat, lower high blood pressure, reduce chest pain)
- blood pressure medications
- calcium channel blockers (medication prescribed to treat high blood pressure, chest pain, some types of irregular heartbeat and stroke, and some non-cardiac diseases)
- diuretics (drugs that promote the formation and secretion of urine)
- iron or calcium supplements
- narcotics (potentially addictive drugs that relieve pain and cause mood changes)
- tricyclic antidepressants (medications prescribed to treat chronic pain, depression, headaches, and other illnesses)

An adult who is constipated may feel bloated, have a **headache**, swollen abdomen, or pass rock-like feces or strain, bleed, or feel pain during bowel movements. A constipated baby may strain, cry, draw the legs toward the abdomen, or arch the back when having a bowel movement.

Diagnosis

Everyone becomes constipated once in a while, but a doctor should be notified if significant changes in bowel patterns last for more than a week or if symptoms continue more than three weeks after increasing activity and fiber and fluid intake. Medical examinations and tests are often given during the diagnosis of constipation.

Examination

The patient's observations and medical history help a primary care physician diagnose constipation. The doctor may perform a rectal examination—using a gloved, lubricated finger to feel if there is a hardened mass in the abdomen.

Physical and psychological assessments and a detailed history of bowel habits are especially important when an elderly person complains of constipation.

Tests

Diagnostic procedures may include a **barium enema**, which reveals blockage inside the intestine, laboratory analysis of blood and stool samples for internal bleeding or other symptoms of systemic disease, and a **sigmoidoscopy** (examination of the sigmoid [lower] area of the colon with a flexible tube equipped with a magnifying lens). A **colonoscopy** may be necessary when one or more obstructions may lie somewhere within the entire length of the colon.

Treatment

If changes in diet and activity fail to relieve occasional constipation, an over-the-counter laxative may be used for a few days. Preparations that soften stools or add bulk (bran, psyllium) work more slowly but are safer than Epsom salts and other harsh laxatives or herbal laxatives containing senna (*Cassia senna*) or buckthorn (*Rhamnus purshianna*), which can harm the nerves and lining of the colon.

Fiber supplements containing psyllium (*Plantago psyllium*) usually become effective within about 48 hours and can be used every day without causing dependency. Powdered flaxseed (*Linium usitatissimum*) works the same way. Insoluble fiber, like wheat or oat bran, is as effective as psyllium but may initially give the patient gas.

Pregnant women should never use a laxative without consulting their doctor. Neither should anyone who is experiencing abdominal pain, nausea, or **vomiting**.

A warm-water or mineral oil enema can relieve constipation, and a non-digestible sugar (lactulose) or special electrolyte solution is recommended for adults and older children with stubborn symptoms. If a patient has an impacted bowel, the doctor inserts a gloved finger into the rectum and gently dislodges the hardened feces.

Alternatives

Initially, alternative practitioners suggest that the patient drink an adequate amount of water each day (six to eight glasses), exercise on a regular basis, and eat a diet high in soluble and insoluble fibers. Soluble fibers include pectin, flax, and gums; insoluble fibers include psyllium and bran from grains such as wheat and oats. Fresh fruits and vegetables contain both soluble and insoluble fibers. Castor oil, applied topically to the abdomen and covered by a heat source (a heating pad or hot water bottle) can help relieve constipation when used nightly for 20 to 30 minutes.

Acupressure

This needle-free form of **acupuncture** is said to relax the abdomen, ease discomfort, and stimulate regular bowel movements when diet and exercise fail to do so. After lying down, individuals close their eyes and take a deep breath. For two minutes, they apply gentle fingertip pressure to a point about 2.5 in. (6.4 cm) below the navel.

Acupressure can also be applied to the outer edges of one elbow crease and maintained for 30 seconds before pressing the crease of the other elbow. This should be done three times a day to help relieve constipation.

Aromatherapy

Six drops of rosemary (*Rosmarinus officinalis*) and six drops of thyme (*Thymus* spp.) diluted by 1 oz. (0.3 dl) of almond oil, olive oil, or another carrier oil can relieve constipation when used to massage the abdomen.

Herbal therapy

A variety of herbal therapies can be useful in the treatment of constipation. Several herbs, including chamomile (*Matricaria recutita*), dandelion (*Taraxacum mongolicum*), and burdock (*Arctium lappa*), act as bitters, stimulating the movement of the digestive and excretory systems. There are also laxative-type herbs that assist with bowel movement. Two of these are senna (*Cassia senna*) and buckthorn (*Rhamnus purshiana*). These laxative-like herbs are stronger acting on elimination than bitters and can sometimes cause cramping (mixing them with a calming herb such as fennel or caraway can help reduce cramping). Both senna and buckthorn are powerful herbs that are best used with direction from an experienced practitioner since they can have adverse side effects and individuals who use them may become dependent on them.

Homeopathy

Homeopathy (another type of alternative medicine) also may offer assistance with constipation. There are acute remedies for constipation that can be found in one of the many home remedy books on **homeopathic medicine**. A constitutional prescription can help rebalance someone who is struggling with constipation.

Massage

Massaging the leg from knee to hip in the morning, at night, and before trying to move the bowels is said to relieve constipation. There is also a specific Swedish massage technique that can help relieve constipation.

Yoga

The knee-chest position, said to relieve gas and stimulate abdominal organs, involves the following:

- standing straight with arms at the sides
- lifting the right knee toward the chest
- grasping the right ankle with the left hand
- pulling the leg as close to the chest as possible
- holding the position for about eight seconds
- repeating these steps with the left leg

The cobra position, which can be repeated as many as four time a day, involves the following:

- lying on the stomach with legs together
- placing the palms just below the shoulders, holding elbows close to the body
- inhaling then lifting the head (face forward) and chest off the floor
- keeping the navel in contact with the floor
- looking as far upward as possible
- holding this position for three to six seconds
- exhaling and lowering the chest

Prognosis

Changes in diet and exercise usually eliminate constipation. However, complications can occur, including those involving such conditions as anal fissures (breaks or tears in the skin of the anal canal), hemorrhoids, fecal impaction (solid, immobile mass of human feces that develop in the rectum), and **rectal prolapse** (degrading of the structure of a section of the rectum wall).

Prevention

Most Americans consume between 0.4 and 0.6 oz. (11 and 18 g) of fiber each day. Consumption of a well-balanced diet with plenty of fiber is essential to prevent constipation. Sufficient amounts of fiber—at least 1.2 oz (35 g) of fiber (an amount equal to five servings of fruits and vegetables) and a large bowl of high-fiber cereal—and between six and eight glasses—1 to 1.5 qt (0.9 to 1.4 L)—of water each day can generally prevent constipation.

Daily use of 500 mg of vitamin C and 400 mg of magnesium may help to prevent constipation. Sitting on the toilet for 10 minutes at the same time every day, preferably after a meal, can induce regular bowel movements. This may not become effective

Contact dermatitis

Definition

Contact **dermatitis** is the name for any skin inflammation that occurs when the skin's surface comes in contact with a substance originating outside the body. There are two kinds of contact dermatitis, irritant and allergic.

Demographics

At any given time in the United States, 2% of the population will have contact dermatitis. This condition accounts for between 4% and 7% of all visits to the dermatologist. Women are twice as likely as men to develop contact dermatitis, and are at highest risk immediately after giving birth.

Description

Contact dermatitis is a skin irritation that manifests as a rash. Thousands of natural and man-made substances can cause contact dermatitis, which is the most common skin condition requiring medical attention and the foremost source of work-related disease.

The abdomen of a male patient afflicted with contact dermatitis, triggered by an allergic reaction to a nickel belt buckle. *(Custom Medical Stock Photo, Inc.)*

Risk factors

Florists, domestic workers, hairdressers, food preparers, and employees in industry, construction, and health care are the people most at risk of contracting work-related contact dermatitis.

Causes and symptoms

Irritant contact dermatitis (ICD) is the more commonly reported of the two kinds of contact dermatitis, and is seen in about 80% of cases. It can be caused by soaps, detergents, solvents, adhesives, fiberglass, and other substances that are able to directly injure the skin. Most attacks are slight and confined to the hands and forearms, but can affect any part of the body that comes in contact with an irritating substance. The symptoms can take many forms: redness, **itching**, crusting, swelling, blistering, oozing, dryness, scaliness, thickening of the skin, and a feeling of warmth at the site of contact. In extreme cases, severe blistering can occur and open sores can form. Jobs that require frequent skin exposure to water, such as hairdressing and food preparation, can make the skin more susceptible to ICD.

Allergic contact dermatitis (ACD) results when repeated exposure to an allergen (an allergy-causing substance) triggers an immune response that inflames the skin. Tens of thousands of drugs, pesticides, cosmetics, food additives, commercial chemicals, and other substances have been identified as potential allergens. Fewer than 30, however, are responsible the majority of ACD cases. Common culprits include **poison ivy**, **poison oak**, and poison sumac; fragrances and preservatives in cosmetics and personal care products; latex items such as gloves and **condoms**; and formaldehyde. Many people find that they are allergic to the nickel in inexpensive jewelry. ACD is usually confined to the area of skin that comes in contact with the allergen, typically the hands or face. Symptoms range from mild to severe and resemble those of ICD; a patch test may be needed to determine which kind of contact dermatitis a person is experiencing.

Diagnosis

Examination

Diagnosis begins with a **physical examination** and asking the patient questions about his or her health and daily activities. When contact dermatitis is suspected, the doctor attempts to learn as much as possible about the patient's hobbies, workplace duties, use of medications and cosmetics, etc.–anything that might shed light on the source of the disease. In some cases, an examination of the home or workplace is undertaken. If the dermatitis is mild, responds well to treatment, and does not recur, ordinarily the investigation is at an end. More difficult cases require patch testing to identify the allergen.

Tests

Patch testing is used to rule out ICD and determine which substances cause an allergic reaction. Most of the TRUE test is used, as it allows testing of multiple substances. A small amount of various diluted chemicals are applied to the skin and covered for two days. Forty-eight hours later, the covering is removed and the doctor examines the patch areas for a reaction. The area is examined again at 72 hours and in one week. Identifying the allergen may require repeated testing. If the TRUE test chemicals do not cause a reaction, additional specialized testing may be required. Patch testing works only with ACD, although it is considered an essential step in ruling out ICD.

Treatment

The best treatment for contact dermatitis is to identify the allergen or irritating substance and avoid

WWW.BOOKBAZ.IR

KEY TERMS

Allergen—A foreign substance that causes an allergic reaction in some sensitive people but not in most others.

Antibiotics—Substances used against microorganisms that cause infection.

Corticosteroids—A group of anti-inflammatory substances often used to treat skin conditions.

Immune response—The protective reaction by the immune system against foreign antigens (substances that the body perceives as potentially dangerous). The immune system combats disease by neutralizing or destroying antigens.

further contact with it. If the culprit is, for instance, a cosmetic, avoidance is a simple matter, but in some situations, such as an allergy to an essential workplace chemical for which no substitute can be found, avoidance may be impossible or force the individual to find new work or make other drastic changes in his or her life. Barrier creams and protective clothing such as gloves, masks, and long-sleeved shirts are ways of coping with contact dermatitis when avoidance is impossible, though they are not always effective.

For the symptoms themselves, treatments in mild cases include cool compresses and nonprescription lotions and ointments. When the symptoms are severe, **corticosteroids** applied to the skin or taken orally are used. Contact dermatitis that leads to a bacterial skin infection is treated with **antibiotics**.

Alternatives

Herbal remedies have been used for centuries to treat skin disorders including contact dermatitis. An experienced herbalist can recommend the remedies that will be most effective for an individual's condition. Among the herbs often recommended are:

- burdock (*Arctium lappa*) minimizes inflammation and boosts the immune system. It is taken internally as a tea or tincture (a concentrated herbal extract prepared with alcohol).
- calendula (*Calendula officinalis*) is a natural antiseptic and anti-inflammatory agent. It is applied topically in a lotion, ointment, or oil to the affected area.
- aloe (*Aloe barbadensis*) soothes skin irritations. The gel is applied topically to the affected area.

A homeopath treating a patient with contact dermatitis will do a thorough investigation of the individual's history and exposures before prescribing a remedy. One homeopathic remedy commonly prescribed to relieve the itching associated with contact dermatitis is *Rhus toxicodendron* taken internally three to four times daily.

Poison ivy, poison oak, and poison sumac are common culprits in cases of allergic contact dermatitis. Following exposure to these plants, rash development may be prevented by washing the area with soap and water within 15 minutes of exposure. The leaves of jewelweed (*Impatiens* spp.), which often grows near poison ivy, may neutralize the poison-ivy allergen if rubbed on the skin right after contact. Several topical remedies may help relieve the itching associated with allergic contact dermatitis, including the juice of plantain leaves (*Plantago major*); a paste made of equal parts of green clay and goldenseal root (*Hydrastis canadensis*); a paste made of salt, water, clay, and peppermint (*Mentha piperita*) oil; and calamine lotion.

Prognosis

If the offending substance is promptly identified and avoided, the chances of a quick and complete recovery are excellent. Otherwise, symptom management—not cure—is the best doctors can offer. For some people, contact dermatitis becomes a chronic and disabling condition that can have a profound effect on employability and quality of life.

Prevention

Avoidance of known or suspected allergens or irritating substances is the best prevention. If avoidance is difficult, barrier creams and protective clothing can be tried. Skin that comes in contact with an offending substance should be thoroughly washed as soon as possible.

Contraception

Definition

Contraception (birth control) prevents **pregnancy** by interfering with the normal process of ovulation, fertilization, and implantation. There are different kinds of birth control that act at different points in the process.

Purpose

Every month, a woman's body begins the process that can potentially lead to pregnancy. An egg (ovum) matures, the mucus that is secreted by the cervix (a cylindrical-shaped organ at the lower end of the uterus) changes to be more inviting to sperm, and the lining of the uterus grows in preparation for receiving a fertilized egg. Any woman who wants to prevent pregnancy must use a reliable form of birth control.

Birth control (contraception) is designed to interfere with the normal process and prevent the pregnancy that could result. There are different kinds of birth control that act at different points in the process, from ovulation, through fertilization, to implantation. Each method has its own side effects and risks. Some methods are more reliable than others.

There are more different types of birth control available today than ever. They can be divided into a few groups based on how they work. These groups include:

Various forms of contraception. *(Charles Thatcher/Stone/Getty Images.)*

- Hormonal methods—These use medications (hormones) to prevent ovulation. Hormonal methods include birth control pills (oral contraceptives), Depo Provera injections, and Norplant.
- Barrier methods—These methods work by preventing the sperm from getting to and fertilizing the egg. Barrier methods include the condom, diaphragm, and cervical cap. The condom is the only form of birth control that also protects against sexually transmitted diseases, including HIV (the virus that causes AIDS).
- Spermicides—These medications kill sperm on contact. Most spermicides contain nonoxynyl-9. Spermicides come in many different forms such as jelly, foam, tablets, and even a transparent film. All are placed in the vagina. Spermicides work best when they are used at the same time as a barrier method.
- Intrauterine devices—Intrauterine contraceptive devices (IUDs) are inserted into the uterus, where they stay from one to 10 years. An IUD prevents the fertilized egg from implanting in the lining of the uterus, and may have other effects as well.
- Tubal sterilization—Tubal sterilization is a permanent form of contraception for women. Each fallopian tube is either tied or burned closed. The sperm

MARGARET SANGER AND BIRTH CONTROL

Margaret Sanger and Lillian Fassett, 1917. *(UPI/Corbis-Bettmann.)*

Margaret Sanger (1879–1966) was born Margaret Higgins in Corning, New York. As a child and young adult, she saw firsthand the toll that numerous and difficult pregnancies took on women. Sanger's mother had eleven children and seven miscarriages. She died in 1899 when Sanger was nineteen years old. Sanger believed that her mother's illness and death were preventable side effects of so many pregnancies.

Sanger trained as a nurse and worked on the Lower East Side of Manhattan in the early 1900s when the area was home to many poor immigrant families. In such a difficult environment, the strain of an additional child was often more than a family could bear, and women frequently resorted to attempting to end their unwanted pregnancies on their own or by paying for back-alley abortions. Both desperate measures were extremely dangerous, and many women for whom Sanger cared had been seriously injured by such attempts.

After watching women suffer because they were unable to control their own rate of reproduction, Sanger gave up the practice of nursing to advocate for contraception availability and education. Sanger's mission was both difficult and dangerous. The U.S. Congress had passed the Comstock Act in 1873 criminalizing the distribution of contraceptives and the dissemination of related information, categorizing such information as obscene. Sanger worked openly despite the Comstock laws. She wrote articles, started magazines and journals, and opened clinics that brought information about condoms and diaphragms to women. She also worked internationally to spread information about contraception.

In 1912, Sanger opened the first American clinic dedicated to contraception. A short time later, she and other women working at the clinic were arrested. Sanger was sentenced to thirty days in a workhouse. Thereafter, she was arrested many times during her career. Once, she had to flee to Europe for a few years to avoid the possibility of a long prison sentence. As soon as that indictment was dropped, she returned to the United States and continued her work, armed with additional information she had gained in Europe.

In 1923, Sanger created the American Birth Control League, an organization that eventually became Planned Parenthood. In 1948, Planned Parenthood organization provided grant money to Gregory Pincus to develop the first birth control pill.

Sanger lived to see her dream of women having control their own reproduction become a reality. On May 9, 1960, the first oral contraceptive was approved for sale in the United States. Within five years, approximately 25% of married women of childbearing age had used it. Her court victories helped to pave the way for the legal, safe dissemination of the pill and information for all women about their contraceptive options.

cannot reach the egg, and the egg cannot travel to the uterus.

- Vasectomy—is the male form of sterilization, and should also be considered permanent. In vasectomy, the vas defrens, the tiny tubes that carry the sperm into the semen, are cut and tied off. Thus, no sperm can get into the semen.
- A newer and somewhat controversial form of birth control is emergency contraception. This type is used after unprotected intercourse and sometimes is referred to as the "morning-after pill."

Unfortunately, there is no perfect form of birth control. Only abstinence (not having sexual intercourse) can protect against unwanted pregnancy with 100% reliability. The failure rates, which means the rates of pregnancy, for most forms of birth control are quite low. However, some forms of birth control are more difficult or inconvenient to use than others. In actual practice, the birth control methods that are more difficult or inconvenient have much higher failure rates because they are not used regularly or as prescribed.

Effectiveness of contraceptives: Percentage of women experiencing an unintended pregnancy within first year of typical[1] and perfect[2] contraceptive use

Form of birth control	Typical use	Perfect use
Birth control pills	8.0%	0.3%
Condom, female	21.0%	5.0%
Condom, male	15.0%	2.0%
Depo-Provera® (injection)	3.0%	0.3%
Diaphragm	16.0%	6.0%
Intrauterine devices (IUDs)	0.8%	0.6%
Spermicides	29.0%	18.0%

[1]Effectiveness based on average or typical usage.
[2]Effectiveness based on perfect or correct usage.

(Table by PreMediaGlobal. © Cengage Learning®.)

Description

Most forms of birth control have one thing in common. They are only effective if used faithfully. Birth control pills will work only if taken every day; the diaphragm is effective only if used during every episode of sexual intercourse. The same is true for **condoms** and the cervical cap. Some methods automatically work every day. These methods include Depo Provera, Norplant, the IUD, and tubal sterilization.

There are many different ways to use birth control. They can be divided into several groups:

- By mouth (oral)—Birth control pills must be taken by mouth every day.
- Injected—Depo Provera is a hormonal medication that is given by injection every three months.
- Implanted—Norplant is a long-acting hormonal form of birth control that is implanted under the skin of the upper arm.
- Vaginal—Spermicides and barrier methods work in the vagina.
- Intrauterine—The IUD is inserted into the uterus.
- Surgical—Tubal sterilization is a form of surgery. A doctor must perform the procedure in a hospital or surgical clinic. Many women need general anesthesia.

The methods of birth control differ from each other in the timing of when they are used. Some methods of birth control must be used specifically at the time of sexual intercourse (condoms, diaphragm, cervical cap, spermicides). **Emergency contraception** must be started as soon as possible after intercourse and no more than 72 hours after. All other methods of birth control (hormonal methods, IUDs, tubal sterilization) must be working all the time to provide protection.

Precautions

There are risks associated with certain forms of birth control. Some of the risks of each method appear in the following list:

- Birth control pills—The hormone (estrogen) in birth control pills can increase the risk of heart attack in women over 35, particularly those who smoke. Certain women cannot use birth control pills.
- IUD—The IUD can increase the risk of serious pelvic infection. The IUD can also injure the uterus by poking into or through the uterine wall. Surgery might be needed to fix this.
- Tubal sterilization—"Tying the tubes" is a surgical procedure and has all the risks of any other surgery, including those associated with anesthesia, as well as infection and bleeding.
- Emergency contraceptive pills should not be used regularly for birth control. They can interrupt the menstrual cycle and are not 100% effective. If the emergency contraception fails, an ectopic pregnancy can occur.

Preparation

No specific preparation is needed before using contraception. However, a woman must be sure that she is not already pregnant before using a hormonal method or having an IUD placed.

Aftercare

No aftercare is needed.

Risks

Many methods of birth control have side effects. Knowing the side effects can help a woman to determine which method of birth control is right for her.

- Hormonal methods—The hormones in birth control pills, Depo Provera, and Norplant can cause changes in menstrual periods, changes in mood, weight gain, acne, and headaches. In addition, it may take many months to begin ovulating again once a woman stops using Depo Provera or Norplant.
- Barrier methods—A woman must insert the diaphragm in just the right way to be sure that it works properly. Some women get more urinary tract infections if they use a diaphragm. This is

WWW.BOOKBAZ.IR

KEY TERMS

Fallopian tubes—The thin tubes that connect the ovary to the uterus. Ova (eggs) travel from the ovary to the uterus. If the egg has been fertilized, it can implant in the uterus.

Fertilization—The joining of the sperm and the egg; conception.

Implantation—The process in which the fertilized egg embeds itself in the wall of the uterus.

Ovulation—The release of an egg (ovum) from the ovary.

because the diaphragm can press against the urethra, the tube that connects the bladder to the outside.

- Spermicides—Some women and men are allergic to spermicides or find them irritating to the skin.
- IUD—The IUD is a foreign body that stays inside the uterus, and the uterus tries to get it out. A woman may have heavier menstrual periods and more menstrual cramping with an IUD in place.
- Tubal sterilization—Some women report increased menstrual discomfort after tubal ligation. It is not known if this is related to the tubal ligation itself.

There is no perfect form of birth control. Every method has a small failure rate and side effects. Some methods carry additional risks. However, every method of birth control can be effective if used properly.

Contractures

Definition

Contractures are the chronic loss of joint motion due to structural changes in non-bony tissue. These non-bony tissues include muscles, ligaments, and tendons.

Description

Contractures can occur at any joint of the body. This joint dysfunction may be a result of **immobilization** from injury or disease; nerve injury, such as spinal cord damage and **stroke**; or muscle, tendon, or ligament disease.

Causes and symptoms

There are a number of pathologies and diseases that can lead to joint contractures. The primary causes resulting in a joint contraction are muscle imbalance, **pain**, prolonged bed rest, and immobilization. Because of the frequency of **fractures** and surgery, immobilization is the most frequent cause of joint contractures. Symptoms include a significant loss of motion to any specific joint that results in immobility. If the contracture is of a significant degree, pain can result even without any voluntary joint movement.

Diagnosis

Manual testing of joint mobility by a healthcare professional skilled in joint mobilization techniques (e.g., a physical therapist) will identify indications of restricted structures within the joint. Measuring the motion of the joint with a device termed a "goniometer" can be useful if the decrease of motion can be shown to be a proven result of a joint contracture. X rays can be of some benefit in the diagnosis of contractures, because a visible decrease in joint space may indicate a tight, contracted joint. Most physicians will make the diagnosis after a thorough **physical examination** involving physical and manual testing of the joint motion.

Treatment

Manual techniques

Joint mobilization and stretching of soft tissues is a common technique used to increase joint elasticity. Structures are stretched in similar directions to those which take place upon normal joint motion. Some healthcare professionals may use some form of heat prior to the stretching and mobilization. If appropriate, **exercise** may follow manual techniques to help maintain the additional motion achieved.

Mechanical techniques

Devices known as continuous passive motion machines are very popular, especially following surgery of joints. Continuous passive motion machines (CPM) are specifically adjusted to each individual's need. This method is administered within the first 24–

KEY TERMS

Mobilization—Making movable, restoring the power of motion in a joint. Movement that increases joint mobility.

Muscle tone—Also termed tonus; the normal state of balanced tension in the tissues of the body, especially the muscles.

72 hours after the injury or surgery. The joint is mechanically moved through the patient's tolerable motion. CPM machines have been proved to accelerate the return motion process, allowing patients more function in less time.

Casting or splinting

Casting or splinting techniques are used to provide a constant stretch to the soft tissues surrounding a joint. It is most effective when used to increase motion of a joint from prolonged immobilization. It is also popular for treating contractures resulting from an increase in muscle tone from nerve injury. After an initial holding cast is applied for 7 to 10 days, a series of positional casts are applied at weekly intervals. Before the application of each new cast, the joint is moved as much as can be tolerated by the patient, and measured by a goniometer. When as much motion as possible is obtained after stretching, another final cast is applied to maintain the newly acquired motion.

Surgery

In some cases, the contracture may be severe and not respond to conservative treatment. In this event, manipulation of the joint under a general **anesthesia** may be necessary.

Alternatives

In some areas of the body, **chiropractic** techniques have been found to be useful to improve motion. **Massage therapy** can be beneficial by promoting additional circulation to joint structures, causing better elasticity. **Yoga** can help prevent as well as rehabilitate a contracture and can facilitate the return of joint mobility.

Prognosis

Prognosis of contractures will depend upon the cause of the contracture. In general, the earlier the treatment for the contracture begins, the better the prognosis.

Prevention

Prevention of contractures and deformities from **spinal cord injury**, fracture, and immobilization is achieved through a program of positioning, splinting if appropriate, and range-of-motion exercises either manually or mechanically aided. These activities should be started as early as possible for optimal results.

Cooling treatments

Definition

Cooling treatments lower body temperature in order to relieve **pain**, swelling, constriction of blood vessels, and to decrease the liklihood of cellular damage by slowing the metabolism. Sponge baths, cold compresses, and cold packs are all wet cooling treatments. Dry treatments, such as ice bags and chemical cold packs, are also used to lower body temperature.

Purpose

The most common reason for cooling a body is **fever** or hyperthermia (extremely high fever). The body can sustain temperatures up to 104°F (40°C) with relative safety; however, when temperatures rise above 104°F (40°C), damage to the brain, muscles, blood, and kidneys is increasingly likely. Cooling treatments are also applied immediately following sprains, **bruises**, **burns**, eye injuries, and **muscle spasms** to help alleviate the resulting swelling, pain, and discoloration of the skin.

WWW.BOOKBAZ.IR

Cooling treatments slow chemical reactions within the body. For this reason, cooling tissues below normal temperature (98.6°F/37°C) can prevent injury from inadequate oxygen or **nutrition**. Cold water **drowning** victims suffering from **hypothermia** (cooling of the body below its normal temperature) have been successfully resuscitated after long periods underwater without medical complications because of this effect. For the past 40 years, heart surgeons have been experimenting with hypothermia to protect tissues from lack of blood circulation during an operation. Neurosurgeons are also working with hypothermia to protect the very sensitive brain tissues during periods of absent or reduced blood flow.

Description

Depending on the medical need, various cooling methods are used.

- Cold packs and ice bags are placed on a localized site and provide topical relief. These compresses should be covered with a waterproof material to protect the skin. Repeated treatments produce the desired pain and swelling relief.
- Cold treatments are placed on the groin and under the arms to treat hyperthermia. Treatments are refreshed periodically until the appropriate temperature is attained.
- A tepid sponge bath relieves fever without cooling the body too fast; 80°F is still 20°F below body temperature and yet warm enough not to drive blood from the skin, thereby preventing the cooling from getting to the body's core. Limbs are bathed first and then the chest, abdomen, back, and buttocks.
- Perfusion of isolated regions like the brain by using cooled blood is an experimental treatment, offering promising results for the treatment of stroke.

Preparation

Topical treatments are prepared with ice, cold water (59°F/15°C), and chemical cold packs. Tepid baths should be 80–93°F (26.7–34°C).

Risks

Small children, adults with circulation problems, and the elderly are all at risk of tissue damage. Rapid cooling causes chills, which in effect raise the body's temperature by raising its metabolism. **Blood clots** may form from thickened blood caused by the temperature change.

Coombs' tests

Definition

Coombs' tests are blood tests that identify the causes of anemia.

Purpose

Anemia, which literally means no blood, refers to blood with abnormally low oxygen-carrying capacity. The hemoglobin in red blood cells carries oxygen. One of the many causes of anemia is destruction of red blood cells, a process called hemolysis (*hemo* means blood and *lysis* means disintegration). A simple blood count detects anemia. Even the test done before a **blood donation** can identify anemia. To detect hemolysis requires other tests. The Coombs' tests are conducted in order to determine the cause of anemia.

One characteristic of hemolysis is the autoimmune response against the body's red blood cells. Instead of protecting the body from outside agents, the immune system attacks parts of its own body with a deluge of antibodies. Autoimmunity is thought to be the cause of many collagen-vascular diseases, including **rheumatoid arthritis** and **systemic lupus erythematosus**. It is also the cause of the autoimmune hemolytic **anemias**. The Coombs' tests detect the antibodies responsible for the destruction of the red blood cells.

Causes of autoimmune **hemolytic anemia** include:

- drugs such as penicillin, methyldopa (lowers blood pressure), and quinidine (treats heart rhythm disturbances)
- cancers of the lymph system–Hodgkin's disease and lymphomas
- virus infections
- collagen-vascular diseases
- mismatched blood transfusions
- Rh incompatibility between a mother and fetus. (erythroblastosis fetalis)

Many times the cause cannot be identified.

KEY TERMS

Anemia—Reduced oxygen-carrying capacity of the blood, due to too little hemoglobin or too few red blood cells.

Antibody—A protein made by the immune system and used as a weapon against foreign invaders in the body.

Antigen—The chemical that stimulates an immune response.

Collagen-vascular disease—Various diseases inflaming and destroying connective tissue.

Hematologist—Physician who specializes in diseases of the blood.

Hemoglobin—The red pigment in blood that carries oxygen.

Hemolysis—Breaking apart red blood cells.

Rh—A blood typing group, like the ABO system. When a mother is Rh negative and her baby is Rh positive, she may develop antibodies to the baby's blood that will cause it to hemolyze.

Description

There are two Coombs' tests. A direct Coombs' test detects the two different antigens that might induce hemolysis in the patient's red blood cells. An indirect Coombs' test looks for antibodies to someone else's red blood cells in the patient's serum (the blood without the cells). Combining the two tests gives clues to the origin of the hemolysis.

Preparation

No preparation is needed for this test. It will probably be among the second or third set of blood tests done after anemia is diagnosed and there is a suspicion that its cause is hemolysis.

Aftercare

Coombs' tests are done on blood that is drawn from the arm.

Risks

Taking blood for testing is the most common medical procedure performed. The worst complication is a bruise at the site of the puncture or punctures. It is extremely rare for the needle to injure an important structure such as an artery or a nerve.

Results

If the Coombs' tests are negative, the anemia is unlikely to be autoimmune, and the hematologist will have to search elsewhere for a cause.

Abnormal results

If the test is positive, the antigens that react will narrow the search for a cause. Coombs' tests are also done for blood **transfusion** reactions to determine why the transfused blood did not match, and when there is a chance a newborn may have an Rh problem.

Cor pulmonale

Definition

Cor pulmonale is an increase in bulk of the right ventricle of the heart, generally caused by chronic diseases or malfunction of the lungs. This condition can lead to **heart failure**.

Description

Cor pulmonale, or pulmonary **heart disease**, occurs in 25% of patients with **chronic obstructive pulmonary disease** (COPD). In fact, about 85% of patients diagnosed with cor pulmonale have COPD. Chronic **bronchitis** and **emphysema** are types of COPD. High blood pressure in the blood vessels of the lungs (**pulmonary hypertension**) causes the enlargement of the right ventricle. In addition to COPD, cor

WWW.BOOKBAZ.IR

pulmonale may also be caused by lung diseases, such as **cystic fibrosis**, **pulmonary embolism**, and pneumoconiosis. Loss of lung tissue after **lung surgery** or certain chest-wall disturbances can produce cor pulmonale, as can neuromuscular diseases, such as **muscular dystrophy**. A large pulmonary thromboembolism (blood clot) may lead to acute cor pulmonale.

Causes and symptoms

Any respiratory disease or malfunction that affects the circulatory system of the lungs may lead to cor pulmonale. These circulatory changes cause the right ventricle to compensate for the extra work required to pump blood through the lungs. The right ventricle has thin walls and is crescent-shaped. The resulting pressure causes the right ventricle to dilate and bulge, eventually leading to its failure.

Cor pulmonale should be expected in any patient with COPD and other respiratory or neuromuscular diseases. Initial symptoms of cor pulmonale may actually reflect those of the underlying disease. These may include chronic coughing, **wheezing**, weakness, **fatigue**, and **shortness of breath**. **Edema** (abnormal buildup of fluid), weakness, and discomfort in the upper chest may be evident in cor pulmonale.

Diagnosis

An electrocardiograph (EKG) will show signs such as frequent premature contractions in the atria or ventricles. Chest x rays may show enlargement of the right descending pulmonary artery. This sign, along with an enlarged main pulmonary artery, indicates pulmonary artery **hypertension** in patients with COPD. **Magnetic resonance imaging** (MRI) is often the preferred method of diagnosis for cor pulmonale because it can clearly show and measure volume of the pulmonary arteries. Other tests used to support a diagnosis of cor pulmonale may include arterial **blood gas analysis**, **pulmonary function tests**, and **hematocrit**.

Treatment

Treatment of cor pulmonale is aimed at increasing a patient's **exercise** tolerance and improving oxygen levels of the arterial blood. Treatment is also aimed at the underlying condition that is producing cor pulmonale. Common treatments include **antibiotics** for respiratory infection; anticoagulants to reduce the risk of thromboembolism; and digitalis, oxygen, and **phlebotomy** to reduce red blood cell count. A low-salt diet and restricted fluids are often prescribed.

KEY TERMS

Ventricle—A cavity, as in the brain or heart. The right ventricle of the heart drives blood from the heart into the pulmonary artery, which supplies blood to the lungs.

Alternatives

Co-management of the patient with cor pulmonale should be coordinated between the medical doctor and the alternative practitioner. The first step in treatment is to determine the cause of the condition and to evaluate all organ systems of the body. Dietary considerations, for example, a low-salt diet and reduced fluid intake aimed at reducing the edema associated with cor pulmonale, can be supportive aspects of treatment.

Prognosis

The prognosis for cor pulmonale is poor, particularly because it occurs late in the process of serious disease.

Prevention

Cor pulmonale is best prevented by prevention of COPD and other irreversible diseases that lead to heart failure. **Smoking** cessation is critically important. Carefully following the recommended course of treatment for the underlying disease may help prevent cor pulmonale.

Corneal abrasion

Definition

A corneal abrasion is a worn or scraped-off area of the outer, clear layer of the eye (cornea).

Demographics

The exact incidence of corneal abrasions is not known; many are work-related; many result in time lost from work. In work-related injuries, men in their twenties are most likely to experience a corneal abrasion.

Description

The cornea is the clear, dome-shaped outer area of the eye. It lies in front of the colored part of the eye (iris) and the black hole in the iris (pupil). The outermost layer of the eyeball consists of the cornea and the white part of the eye (sclera). A corneal abrasion is a superficial cut or scrape on the cornea. A corneal abrasion is not as serious as a corneal ulcer, which is generally deeper and more severe than an abrasion.

Causes and symptoms

A corneal abrasion is usually the result of direct injury to the eye, often from a fingernail scratch, makeup brushes, **contact lenses**, foreign body, or even twigs. Patients often complain of feeling a foreign body in their eye, and they may have **pain**, sensitivity to light, or tearing.

Diagnosis

Examination

Ophthalmologists and optometrists who treat eye disorders are well qualified to diagnose corneal abrasions. The doctor will check the patient's vision (visual acuity) in both eyes with an eye chart. A patient history will also be taken, which may help to determine the cause of the abrasion. A slit lamp, which is basically a microscope and light source, will allow the doctor to see the abrasion. Fluorescein, a yellow dye, may be placed into the eye to determine the extent of the abrasion. The fluorescein will temporarily stain the affected area.

Treatment

The cornea has a remarkable ability to heal itself, so treatment is designed to minimize complications. If the abrasion is very small, the doctor might just suggest an eye lubricant and a follow-up visit the next day. A very small abrasion should heal in one to two days; others usually in one week. However, to avoid a possible infection, an antibiotic eye drop may be prescribed. Sometimes additional eye drops may make the eye feel more comfortable. Depending upon the extent of the abrasion, some doctors may patch the affected eye. It is important to go for the follow-up checkup to make sure an infection does not occur. Use of contact lenses should not be resumed without the doctor's approval.

KEY TERMS

Abrasion—An area of the body whose surface has been worn away by some abnormal process.

Cornea—The transparent structure on the front part of the eye.

Recurrent corneal erosion (RCE)—Repeated erosion of the cornea. May be a result of inadequate healing of a previous abrasion.

Slit lamp—An instrument used to examine the front of the eye.

Prognosis

In typical cases, the prognosis is good. The cornea will heal itself, usually within several days. A very deep abrasion may lead to scarring. If the abrasion does not heal properly, a recurrent corneal erosion (RCE) may result months or even years later. The symptoms are the same as for an abrasion (e.g., tearing, foreign body sensation, and blurred vision), but it will keep occurring. Similar or additional treatment for the RCE may be necessary.

Prevention

Everyone should wear eye protection whenever this is recommended. This should be standard practice when using power tools and playing certain sports. Goggles should even be worn when mowing the lawn, because a twig can be thrown upward toward the face. Contact lens wearers should be careful to follow their doctor's instructions on caring for and wearing their lenses. Ill-fitting or dirty lenses could lead to an abrasion, so patients should go for their prescribed checkups.

Corneal keratoplasty *see* **Corneal transplantation**

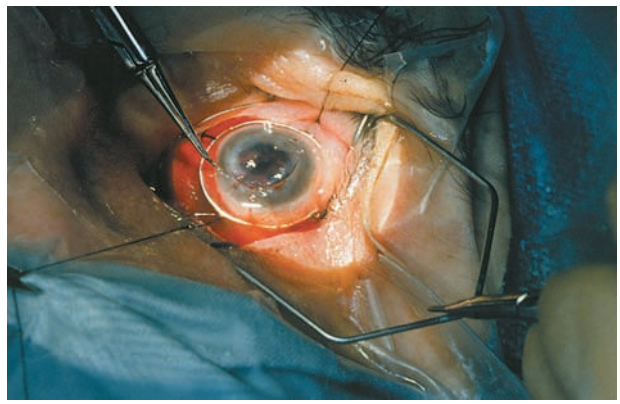
Corneal transplantation

Definition

In corneal transplant, also known as keratoplasty, a patient's damaged cornea is replaced by the cornea from the eye of a human cadaver. This is the single most common type of human **transplant surgery** and has the highest success rate. Eye banks acquire and store eyes from donor individuals largely to supply the need for transplant corneas.

Purpose

Corneal transplant is used when vision is lost in an eye because the cornea has been damaged by disease or traumatic injury. Some of the disease conditions that might require corneal transplant include the bulging outward of the cornea (keratoconus), a malfunction of the inner layer of the cornea (Fuchs' dystrophy), and painful swelling of the cornea (pseudophakic bullous keratopathy). Some of these conditions cause cloudiness of the cornea; others alter its natural curvature, which can also reduce the quality of vision.



A corneal transplant in progress. *(© Chet Szymecki/Phototake.—All rights reserved.)*

Injury to the cornea can occur because of chemical **burns**, mechanical **trauma**, or infection by viruses, bacteria, fungi, or protozoa. The herpes virus produces one of the more common infections leading to corneal transplant.

Surgery is only used when damage to the cornea is too severe to be treated with corrective lenses. Occasionally, corneal transplant is combined with other types of eye surgery (such as **cataract surgery**) to solve multiple eye problems in one procedure.

Precautions

Corneal transplant is a very safe procedure that can be performed on almost any patient who would benefit from it. Any active infection or inflammation of the eye usually needs to be brought under control before surgery can be performed.

Description

The cornea is the transparent layer of tissue at the very front of the eye. It is composed almost entirely of a special type of collagen. It normally contains no blood vessels, but because it contains nerve endings, damage to the cornea can be very painful.

In a corneal transplant, a disc of tissue is removed from the center of the eye and replaced by a corresponding disc from a donor eye. The circular incision is made using an instrument called a trephine. In one form of corneal transplant (penetrating keratoplasty), the disc removed is the entire thickness of the cornea and so is the replacement disc. Over 90% of all corneal transplants in the United States are of this type. In lamellar keratoplasty, on the other hand, only the outer layer of the cornea is removed and replaced.

KEY TERMS

Cadaver—The human body after death.

Cataract—A condition of cloudiness of the lens of the eye.

Cornea—The transparent layer of tissue at the very front of the eye.

Corticosteroids—Synthetic hormones widely used to fight inflammation.

Epikeratophakia—A procedure in which the donor cornea is attached directly onto the host cornea.

Epithelial cells—Cells that form a thin surface coating on the outside of a body structure.

Fibrous connective tissue—Dense tissue found in various parts of the body containing very few living cells.

Fuchs' dystrophy—A hereditary disease of the inner layer of the cornea. Treatment requires penetrating keratoplasty. The lens of the eye may also be affected and require surgical replacement at the same time as the cornea.

Glaucoma—A vision defect caused when excessive fluid pressure within the eye damages the optic nerve.

Histocompatibility antigens—Proteins scattered throughout body tissues that are unique for almost every individual.

Keratoconus—An eye condition in which the cornea bulges outward, interfering with normal vision. Usually both eyes are affected.

Pseudophakic bullous keratopathy—Painful swelling of the cornea occasionally occurring after surgery to implant an artificial lens in place of a lens affected by cataract.

Retinal detachment—A serious vision disorder in which the light-detecting layer of cells inside the eye (retina) is separated from its normal support tissue and no longer functions properly.

Trephine—A small surgical instrument that is rotated to cut a circular incision.

The donor cornea is attached with extremely fine sutures. Surgery can be performed under **anesthesia** that is confined to one area of the body while the patient is awake (local anesthesia) or under anesthesia that places the entire body of the patient in a state of unconsciousness (general anesthesia). Surgery requires 30–90 minutes.

Over 40,000 corneal transplants are performed in the United States each year. Medicare offers reimbursement for corneal transplants.

A less common but related procedure called epikeratophakia involves suturing the donor cornea directly onto the surface of the existing host cornea. The only tissue removed from the host is the extremely thin epithelial cell layer on the outside of the host cornea. There is no permanent damage to the host cornea, and this procedure can be reversed. It is usually employed in children. In adults, the use of **contact lenses** can usually achieve the same goals.

Preparation

No special preparation for corneal transplant is needed. Some eye surgeons may request the patient have a complete **physical examination** before surgery. The patient may also be asked to skip breakfast on the day of surgery.

Aftercare

Corneal transplant is often performed on an outpatient basis, although some patients need brief hospitalization after surgery. The patient will wear an eye patch at least overnight. An eye shield or glasses must be worn to protect the eye until the surgical wound has healed. Eye drops will be prescribed for the patient to use for several weeks after surgery. These drops include **antibiotics** to prevent infection as well as **corticosteroids** to reduce inflammation and prevent graft rejection.

For the first few days after surgery, the eye may feel scratchy and irritated. Vision will be somewhat blurry for as long as several months.

Sutures are often left in place for six months, and occasionally for as long as two years.

Risks

Corneal transplants are highly successful, with over 90% of operations in United States achieving restoration of sight. However, there is always some risk associated with any surgery. Complications that can occur include infection, **glaucoma**, **retinal detachment**, cataract formation, and rejection of the donor cornea.

Graft rejection occurs in 5–30% of patients, a complication possible with any procedure involving

WWW.BOOKBAZ.IR

tissue transplantation from another person (allograft). Allograft rejection results from a reaction of the patient's immune system to the donor tissue. Cell surface proteins called histocompatibility antigens trigger this reaction. These antigens are often associated with vascular tissue (blood vessels) within the graft tissue. Since the cornea normally contains no blood vessels, it experiences a very low rate of rejection. Generally, **blood typing** and **tissue typing** are not needed in corneal transplants, and no close match between donor and recipient is required. Symptoms of rejection include persistent discomfort, sensitivity to light, redness, or a change in vision.

If a rejection reaction does occur, it can usually be blocked by steroid treatment. Rejection reactions may become noticeable within weeks after surgery, but may not occur until 10 or even 20 years after the transplant. When full rejection does occur, the surgery will usually need to be repeated.

Although the cornea is not normally vascular, some corneal diseases cause vascularization (the growth of blood vessels) into the cornea. In patients with these conditions, careful testing of both donor and recipient is performed just as in transplantation of other organs and tissues such as hearts, kidneys, and bone marrow. In such patients, repeated surgery is sometimes necessary in order to achieve a successful transplant.

Cornea donors are carefully screened. Individuals with infectious diseases are not accepted as donors.

Victor Leipzig, PhD

Corneal ulcers

Definition

The cornea, the clear front part of the eye through which light passes, is subject to many infections and to injury from exposure and from **foreign objects**. Infection and injury cause inflammation of the cornea—a condition called **keratitis**. Tissue loss because of inflammation produces an ulcer. The ulcer can either be centrally located, thus greatly affecting vision, or peripherally located. There are about 30,000 cases of bacterial corneal **ulcers** in the United States each year.

A close-up view of an ulcer on cornea. *(Custom Medical Stock Photo, Inc.)*

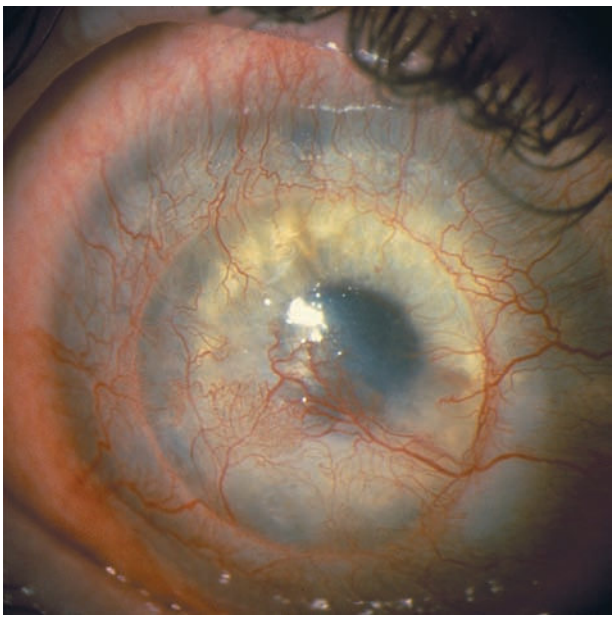
Description

The most common cause of corneal ulcers is germs, but most of them cannot invade a healthy cornea with adequate tears and a functioning eyelid. They gain access because injury has impaired these defense mechanisms. A direct injury from a foreign object inoculates germs directly through the outer layer of the cornea, just as it does to the skin. A caustic chemical can inflame the cornea by itself or so damage it that germs can invade. Improper use of **contact lenses** has become a common cause of corneal injury. Eyelid or tear function failure is the other way to make the eye vulnerable to infection. Tears and the eyelid together wash the eye and prevent foreign material from settling in. Tears contain enzymes and other substances to help protect against infection. Certain diseases dry up tear production, leaving the cornea dry and defenseless. Other diseases paralyze or weaken the eyelids so that they cannot effectively protect and cleanse the eyes.

Causes and symptoms

Viruses, bacteria, fungi, and a protozoan called *Acanthamoeba* can all invade the cornea and damage it under suitable conditions.

- Bacteria from a common conjunctivitis (pink eye) rarely spread to the cornea, but can if untreated.
- Fecal bacteria are more likely to be able to infect the cornea.
- A bacterium called *Pseudomonas aeruginosa*, which can contaminate eyedrops, is particularly able to cause corneal infection.



A close-up view of an abrasion on patient's cornea. *(Custom Medical Stock Photo, Inc.)*

- A group of incomplete bacteria known as *Chlamydia* can be transmitted to the eye directly by flies or dirty hands. One form of chlamydial infection is the leading cause of blindness in developing countries and is known as Egyptian ophthalmia or trachoma. Another type of *Chlamydia* causes a sexually transmitted disease.
- Other sexually transmitted diseases—for example, syphilis—can affect the cornea.

The most common viruses to damage the cornea are adenoviruses and herpes viruses. Viral and **fungal infections** are often caused by improper use of topical **corticosteroids**. If topical corticosteroids are used in a patient with the herpes simplex keratitis, the ulcer can get much worse and blindness could result.

Symptoms are obvious. The cornea is intensely sensitive, so corneal ulcers normally produce severe **pain**. If the corneal ulcer is centrally located, vision is impaired or completely absent. Tearing is present and the eye is red. It hurts to look at bright lights.

Diagnosis

The doctor will take a case history to try to determine the cause of the ulcer. This can include improper use of contact lenses; injury, such as a scratch from a twig; or severe dry eye. An instrument called a slit lamp will be used to examine the cornea. The slit lamp is a microscope with a light source that magnifies the cornea, allowing the extent of the ulcer to be seen. Fluorescein, a yellow dye, may be used to illuminate further detail. If a germ is responsible for the ulcer, identification may require scraping samples directly from the cornea, conjunctiva, and lids, and sending them to the laboratory.

Treatment

A corneal ulcer needs to be treated aggressively, as it can result in loss of vision. The first step is to eliminate infection. Broad spectrum **antibiotics** will be used before the lab results come back. Medications may then be changed to more specifically target the cause of the infection. A combination of medications may be necessary. Patients should return for their follow-up visits so that the doctor can monitor the healing process. The cornea can heal from many insults, but if it remains scarred, **corneal transplantation** may be necessary to restore vision. If the corneal ulcer is large, hospitalization may be necessary.

Prognosis

Treated early enough, corneal infections will usually resolve, perhaps even without the formation of an ulcer. However, left untreated, infections can lead to ulcers and the corneal ulcer can result in scarring or perforation of the cornea. Other problems may occur as well, including **glaucoma**. Patients with certain systemic diseases that impede healing (such as **diabetes mellitus** or **rheumatoid arthritis**) may need more aggressive treatment. The later the treatment, the more damage will be done and the more scarring will result. Corneal transplant is standard treatment with a high probability of success.

Prevention

Attentive care of contact lenses will greatly reduce the incidence of corneal damage and ulceration. Germs that cause no problems in the mouth or on the hands can damage the eye, so contact lens wearers must wash their hands before touching their lenses and must not use saliva to moisten them. Tap water should not be used to rinse the lenses. Contacts should be removed whenever there is irritation and left out until the eyes are back to normal. It is not advisable to wear contact lenses while swimming or in hot tubs. Daily wear contact lenses have been found to be less of a risk than contacts for overnight wear (extended wear). Organisms have been cultured from contact lens cases, so the cases should be rinsed in hot water and allowed to air dry. Cases should be replaced every three months. Patients should follow their doctors' schedules for replacement of the contacts.

Eye protection in the workplace, or wherever tiny particles are flying around, is essential. Ultraviolet

WWW.BOOKBAZ.IR

KEY TERMS

Fluorescein—A fluorescent chemical used to examine the cornea.

Germ—A disease-causing microorganism.

Inflammation—The body's reaction to irritation.

Topical corticosteroids—Cortisone and related drugs used on the skin and in the eye, usually for allergic conditions.

(UV) coatings on glasses or sunglasses can help protect the eyes from the sun's rays. Goggles with UV protection should be worn when skiing or in suntanning salons to protect against UV rays. Prompt attention to any red eye should prevent progressive damage.

For people with inadequate tears, use of artificial tears eyedrops will prevent damage from drying. Eyelids that do not close adequately may temporarily have to be sewn shut to protect the eye until more lasting treatment can be instituted.

Corns and calluses

Definition

Corns and calluses are thick, hardened layers of skin that sometimes develop when skin tries to protect itself against pressure and friction. They are often painful thickenings that form in areas of the skin that are prone to being rubbed by an external object, such as the skin on toes caused from the rubbing of shoes. Corns and calluses most often develop on the feet and toes or the hands and fingers. Most people do not need treatment for corns or calluses; they are simply eliminated by removing the source of pressure or friction. However, people with diabetes or other conditions that cause poor circulation can complicate the removal of corns and calluses. These people often need to seek a physician's assistance.

Description

Corns and calluses are one of the three major foot problems in the United States. The other two are foot infections and toenail problems. Corns and calluses affect about 5% of the population. When skin becomes abnormally thickened the medical condition that results is called hyperkeratosis—simply, thickening of the skin.

Corns and calluses develop on parts of the body that come in contact with objects and materials that apply pressure to those areas. Corns are smaller than calluses. Also called helomas, corns are small, painful, raised bumps on the outer skin layer, usually having a dry, translucent, or waxy appearance. The hard centers of corns are often surrounded by inflamed skin and are shaped like inverted pyramids. Corns generally appear as thick, localized areas with conical or circular shapes. Sharp **pain** occurs whenever downward pressure is applied, and a dull ache may be felt at other times. They form usually on non-weight-bearing areas such as the outside of the little toe or the tops or sides of other toes. Corns may also appear between the fourth and fifth toes. Sometimes corns are also present on the sole of the foot, specifically on the ball of the foot (the metatarsal arch). Women have corns more often than do men, probably because women wear high-heeled shoes and other shoes that are not shaped to fit feet properly.

Calluses are rougher-looking patches of skin, with an appearance of more diffuse, flattened areas of thick skin. Calluses vary widely in shape and size. They occur most often on soles of feet, primarily the heels and balls. Calluses also can appear on the knees and the palms of the hands. However, they can develop on any part of the body that is subject to repeated pressure or irritation. Calluses are usually more than an inch wide—larger than corns. They generally do not hurt unless pressure is applied.

Types of corns

Corns may be termed soft corns (heloma molles) when they appear whitish in color. A soft corn is a small, inflamed patch of skin with a smooth center. Soft corns usually appear between the toes. A hard corn (heloma durums) is a compact lump with a thick core. Hard corns usually form on the tops of the toes, on the outside of the little toe, or on the sole of the foot.

Corns on toes. *(Custom Medical Stock Photo, Inc.)*

A seed corn is the least common type. Occurring only on the heel or ball of the foot, a seed corn consists of a circle of stiff skin surrounding a plug of **cholesterol**.

Types of calluses

A plantar callus is a callus that occurs on the sole of the foot and has a white center. Hereditary calluses, which run in some families, develop where there is no apparent friction and occur most often in children.

Corns or calluses may become painful and/or inflamed. When any of these symptoms happen it is advisable to see a medical professional. It is especially important to visit a doctor if one is diabetic or has poor circulation because a minor problem can quickly develop into a serious one that is difficult to heal.

Demographics

According to the Illinois Podiatric Medical Association (IPMA), approximately 19% of Americans have about 1.4 foot problems each year. Specifically, corns or calluses affect about 5% of the U.S. population. As stated by the IPMA, podiatric physicians provide treatment for about 82% of problems concerning corns and calluses. The association also states that of the three major problems of the foot—infections, toenails, and corns and calluses—people are least likely to receive treatment for corns and calluses than the other two problems. Most people do not seek treatment for corns and calluses.

Causes and symptoms

Corns and calluses form as a way to protect the skin from friction or excessive pressure from outside forces. For instance, corns and calluses may form to prevent injury to skin that is repeatedly pinched, rubbed, or irritated. The most common causes are as follows:

- shoes that are too tight or too loose or have very high heels; they may compress parts of the foot when too tight or may repeatedly slide and rub against the foot if too loose.
- tight socks or stockings; also, wearing shoes without socks can lead to friction on the feet
- deformed toes, such as hammer toe, or other bony prominences in the feet
- abnormalities in gait or movement that cause increased pressure to specific parts of the body, such as finger calluses that develop due to playing musical instruments or working with some equipment
- walking down a long hill or standing or walking on a hard surface for a long time
- using hand tools (without gloves) can cause calluses on the hands and fingers from repeated pressure
- performing jobs or hobbies that cause steady or recurring pressure on the same spot on the body

Symptoms include thick, hard, and/or rough growths on the skin in response to direct pressure. The area of corns and calluses may be dry and appear scaly, flaky, or waxy. They may cause pain or discomfort but may also be painless. Corns and calluses may sometimes cause one to walk differently than normal or perform activities in an unusual manner. Corns may be extremely sore and surrounded by inflamed, swollen skin.

Diagnosis

Corns can be recognized on sight. A family physician or podiatrist may observe the characteristic signs of corns and calluses on the skin. The doctor will rule out other reasons for thickened skin such as cysts and **warts**. Such a medical professional may scrape skin off what seems to be a callus, which may actually be a wart. If the lesion is a wart, it will bleed. A corn or callus will not bleed but will reveal another layer of dead skin.

Treatment

Corns and calluses do not usually require medical attention unless the person who has them has **diabetes mellitus**, poor circulation, or other problems that make self-care difficult.

WWW.BOOKBAZ.IR

Treatment should begin as soon as an abnormality appears. The first step is to identify and eliminate the source of pressure. Placing moleskin pads over corns can relieve pressure, and large wads of cotton, lamb's wool, or moleskin can cushion calluses.

Medicated products may also be used for treatment of corns and calluses. Using hydrocortisone creams or soaking feet in a solution of Epsom salts and very warm water for at least five minutes a day before rubbing the area with a pumice stone will remove part or all of some calluses. However, rubbing corns just makes them hurt more.

Most medicated products used for the treatment of corns and calluses contain the active ingredient of salicylic acid, which is the same ingredient used for wart removal. Salicylic acid is a substance that dissolves the protein keratin, which is why it is part of the group called kerotolyics. Salicylic acid is safe when used according to label instructions. Many products that contain salicylic acid provide it in a strength of 40%. Nonprescription brands that include salicylic acid include Curad Mediplast and Dr. Scholl's Corn/Callus Remover. However, it is always advisable to ask a medical professional before trying such products. People with diabetes or those with fragile skin or poor circulation should definitely seek help from a trusted doctor before using them. These medicated products come in the following forms: applicators, drops, pads, and plasters.

Applying petroleum jelly or lanolin-enriched hand lotion helps keep skin soft, but corn-removing ointments that contain acid can damage healthy skin. These acid-containing products should never be used by pregnant women or by people who are diabetic or who have poor circulation.

A doctor may trim down thickened skin or trim a large corn with a scalpel. Trimming of thickened skin should never be done by anyone but a medical professional because the area can become infected. It is important to see a doctor if the skin of a corn or callus is accidentally cut, because it may become infected. If a corn discharges pus or clear fluid, it is infected. A family physician, podiatrist, or orthopedist may do the following:

- remove (debride) affected layers of skin
- prescribe oral antibiotics to eliminate infection
- drain pus from infected corns
- inject cortisone into the affected area to decrease pain or inflammation
- perform surgery to correct toe deformities or remove bits of bone

Alternatives

Standing and walking correctly can sometimes eliminate excess foot pressure. Several types of bodywork can help correct body imbalances. Bodywork is a term used for any of a number of systems, including **Aston-Patterning**, the **Feldenkrais method**, and **rolfing**, that manipulate the body through massage and movement education.

Aloe (*Aloe barbadensis*) cream is an effective skin softener, and two or three daily applications of calendula (*Calendula officinalis*) salve can soften skin and prevent inflammation. One teaspoon of lemon juice mixed with one teaspoon of dried chamomile (*Martricaria recutita*) tea and one crushed garlic clove helps to dissolve thickened skin.

An Ayurvedic practitioner (a person who practices **Ayurvedic medicine**, a system of traditional medicine practiced originally on the Indian subcontinent) may recommend the following treatment:

- apply each day a paste made by combining one teaspoon of aloe vera gel with half that amount of turmeric (*Circuma longa*)
- bandage overnight
- soak in warm water for 10 minutes every morning
- massage gently with mustard (*Brassica cruciferae*) oil

Prognosis

Most corns and calluses disappear about three weeks after the pressure that caused them is eliminated. They are apt to recur if the pressure returns. Under most conditions, corns and calluses can be treated with home-care remedies or basic medical treatment.

Extreme pain from corns or calluses can change the way a person stands or walks. Such changes can in turn cause pain in the ankle, back, hip, or knee. In some rare cases, surgery may be necessary, especially if infection is present.

Bursitis, a painful, inflamed fluid-filled sac, can develop beneath a corn. An ulcer or broken area within a corn can reach to the bone. Infection can have serious consequences for people who have diabetes or poor circulation. **Hammertoe** and other foot deformities can also cause increased rubbing of the feet inside shoes.

Prevention

Corns and calluses can usually be prevented by avoiding friction-causing activities and wearing shoes that fit properly, are activity-appropriate, and are kept

KEY TERMS

Ayurveda—A system of holistic medicine from India that aims to bring the individual into harmony with nature. It provides guidance regarding food and lifestyle, so that healthy people can stay healthy and people with health challenges can improve their health.

Bursitis—Inflammation of a bursa, a fluid-filled cavity or sac. In the body, bursae are located at places where friction might otherwise develop.

in good repair. Soles and heels that wear unevenly may indicate a need for corrective footwear or special insoles. Socks and stockings should not cramp the toes. Gloves, kneepads, and other protective gear should also be worn as needed.

Feet should be measured, while standing, whenever buying new shoes. It is best to shop for shoes late in the day, when feet are likely to be swollen. It is also important to buy shoes with toe-wiggling room and to try new shoes on both feet.

REVISED BY WILLIAM A. ATKINS, B.B., B.S., M.B.A.

Coronary artery bypass graft surgery

Definition

Coronary artery bypass graft surgery (CABG) is a procedure in which one or more blocked coronary arteries are bypassed by a blood vessel graft to restore normal blood flow to the heart. These grafts usually come from the patient's own arteries and veins located in the leg, arm, or chest.

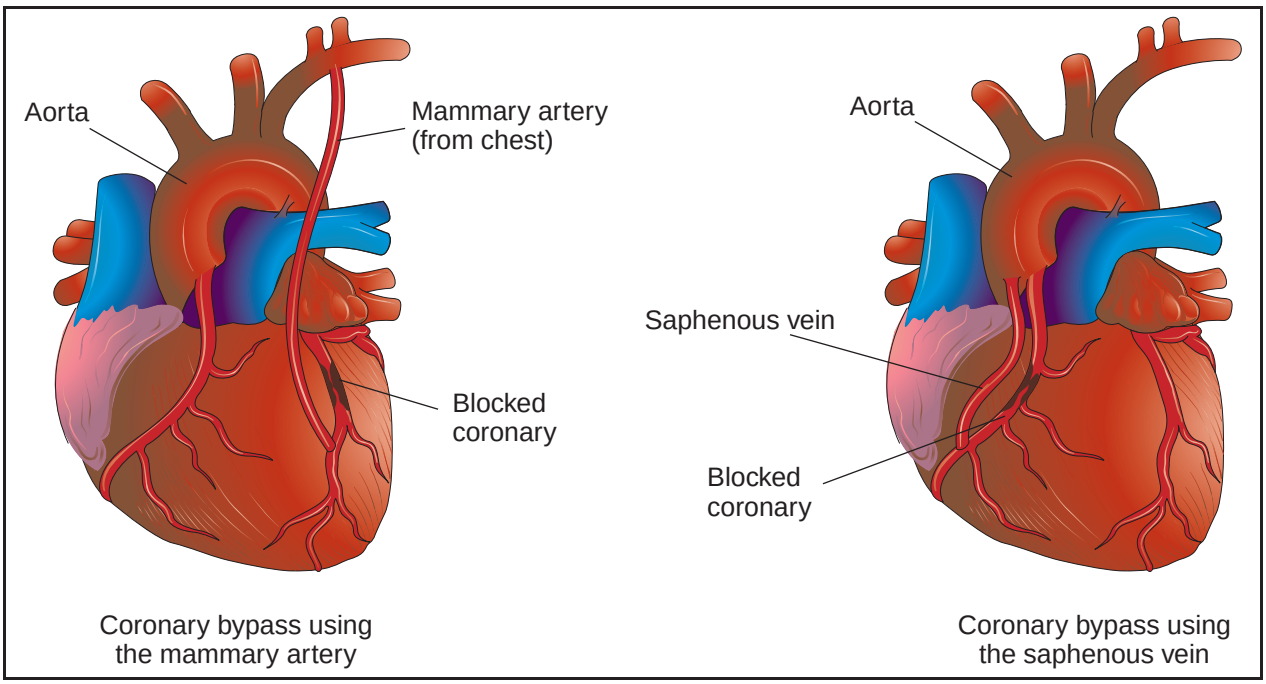
Purpose

Coronary artery bypass graft surgery, also called coronary artery bypass surgery and bypass operation, is performed to restore blood flow to the heart. Doing so relieves chest **pain** and ischemia, improves the patient's quality of life, and, in some cases, prolongs the patient's life. The goals of the procedure are to relieve symptoms of **coronary artery disease**, enable the patient to resume a normal lifestyle, and lower the risk of a **heart attack** or other heart problems.

According to the American Heart Association (AHA), appropriate candidates for coronary artery bypass graft surgery include patients for whom the following applies:

- have blockages in at least two or three major coronary arteries, especially if the blockages are in arteries that feed the heart's left ventricle or are in the left anterior descending artery;
- have angina so severe that even mild exertion causes chest pain;
- have poor left ventricular function; and
- cannot tolerate percutaneous transluminal coronary angioplasty and do not respond well to drug therapy.

WWW.BOOKBAZ.IR



Coronary artery bypass graft surgery builds a detour around one or more blocked coronary arteries with a graft from a healthy vein or artery. The graft goes around the clogged artery (or arteries) to create new pathways for oxygen-rich blood to flow to the heart. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Demographics

The AHA estimated that in the United States in 2005, 469,000 coronary artery bypass procedures were performed on 261,000 individual patients. More than twice as many of these surgeries were performed on men than women. Fifteen thousand of these procedures were performed on people between the ages of 15–44, 188,000 on people between ages 45 and 64, and the remainder on people age 65 and older.

Description

Coronary artery bypass graft surgery builds a detour around one or more blocked coronary arteries with a graft from a healthy vein or artery. The graft goes around the clogged artery (or arteries) to create new pathways for oxygen-rich blood to flow to the heart.

Procedure

After general **anesthesia** is administered, the surgeon removes the veins or prepares the arteries for grafting. The surgeon decides which grafts to use based on the location of the blockage, the amount of blockage, and the size of the patient's coronary arteries. If the saphenous vein is to be used for the graft, a series of incisions are made in the patient's thigh or calf. If the radial artery is to be used for the graft, incisions are made in the patient's forearm. More commonly, a segment of the internal mammary artery is used for the graft, and the incisions are made in the chest wall. The internal mammary arteries are often used because they have shown the best long-term results. The removal of veins or arteries for grafting does not deprive the area from which they are removed of adequate blood flow.

In traditional coronary artery bypass surgery, the surgeon makes an incision down the center of the patient's chest, cuts through the breastbone, and retracts the rib cage open to expose the heart. The patient is connected to a heart-lung bypass machine, also called a cardiopulmonary bypass pump, that takes over for the heart and lungs during the surgery. During this "on-pump" procedure, the heart-lung machine removes carbon dioxide from the blood and replaces it with oxygen. A tube is inserted into the aorta to carry the oxygenated blood from the bypass machine to the aorta for circulation to the body. The heart-lung machine allows heart contractions to be stopped, so the surgeon can operate on a still heart. Aortic clamps are used to restrict blood flow to the area of the heart where grafts will be placed so the heart is blood-free during the surgery. The clamps remain until the grafts are in place.

KEY TERMS

Angina—Also called angina pectoris, chest pain or discomfort that occurs when diseased blood vessels restrict blood flow to the heart.

Angiotensin-converting enzyme (ACE) inhibitor—A drug that lowers blood pressure by interfering with the breakdown of a protein-like substance involved in blood pressure regulation.

Aorta—The main artery that carries blood from the heart to the rest of the body. The aorta is the largest artery in the body.

Artery—A vessel that carries oxygen-rich blood to the body.

Atherectomy—A non-surgical technique for treating diseased arteries with a rotating device that cuts or shaves away obstructing material inside the artery.

Atrium (plural Atria)—The right or left upper chamber of the heart.

Beta blocker—An anti-hypertensive drug that limits the activity of epinephrine, a hormone that increases blood pressure.

Brachytherapy—The use of radiation during angioplasty to prevent the artery from narrowing again (a process called restenosis).

Calcium channel blocker—A drug that lowers blood pressure by regulating calcium-related electrical activity in the heart.

Cardiac rehabilitation—A structured program of education and activity offered by hospitals and other organizations.

Coronary artery disease—Also called atherosclerosis, it is a build-up of fatty matter and debris in the coronary artery wall that causes narrowing of the artery.

Echocardiogram—An imaging procedure used to create a picture of the heart's movement, valves, and chambers.

Graft—To implant living tissue surgically.

Homocysteine—An amino acid normally found in small amounts in the blood.

Ischemia—Decreased blood flow to an organ, usually caused by constriction or obstruction of an artery.

Lipoproteins—Substances that carry fat through the blood vessels for use or storage in other parts of the body.

Mammary artery—A chest wall artery that descends from the aorta and is commonly used for bypass grafts.

Radial artery—An artery located in the arm and used for bypass grafts.

Rotoblation—A non-surgical technique for treating diseased arteries.

Saphenous vein—A long vein in the thigh or calf commonly used for bypass grafts.

Stent—A device made of expandable, metal mesh that is placed (by using a balloon catheter) at the site of a narrowing artery; the stent stays in place to keep the artery open.

Sternum—Also called the breastbone, the sternum is the bone in the chest that is separated during open heart surgery.

Stress test—A test used to determine how the heart responds to stress.

Vein—A blood vessel that returns oxygen-depleted blood from various parts of the body to the heart.

Ventricle—A lower pumping chamber of the heart. There are two ventricles, right and left. The right ventricle pumps oxygen-poor blood to the lungs to be re-oxygenated. The left ventricle pumps oxygen-rich blood to the body.

Some patients may be candidates for minimally invasive coronary artery bypass surgery or for off-pump bypass surgery. During **minimally invasive surgery**, smaller chest and graft removal incisions are used, promoting a quicker recovery and less risk of infection. Off-pump bypass surgery, also called beating heart surgery, is a surgical technique performed while the heart is still contracting (beating). The surgeon uses advanced equipment to stabilize portions of the heart and bypass the blocked artery while the rest of the heart keeps pumping and circulating blood through the body.

After the grafts are prepared, a small opening is made in the diseased coronary artery just below the blockage. Blood will be redirected through this opening once the graft is sewn in place. If a leg or arm vein is used, one end is connected to the coronary artery and the other to the aorta. If a mammary artery is used, one end is connected to the coronary artery while the other is already attached to the aorta and remains in place. The procedure is repeated on as many coronary arteries as necessary. On average, three or four coronary arteries are bypassed during surgery. Blood flow

WWW.BOOKBAZ.IR

is checked to assure the graft supplies adequate blood to the heart.

If the procedure was done on-pump, electric shocks start the heart pumping again after the grafts have been completed. The heart-lung machine is turned off and the blood slowly returns to normal body temperature. After implanting pacing wires and inserting a chest tube to drain fluid, the surgeon closes the chest cavity. Sometimes a temporary pacemaker is attached to the pacing wires to regulate the heart rhythm until the patient's condition improves. After surgery, the patient is transferred to an intensive care unit (ICU) for close monitoring.

Diagnosis/Preparation

Diagnosis

The diagnosis of coronary artery disease is made after the patient's medical history is carefully reviewed, a physical exam is performed, and the patient's symptoms are evaluated. Tests used to diagnose coronary artery disease include:

- electrocardiogram;
- stress tests;
- cardiac catheterization;
- imaging tests such as a chest x ray, echocardiography, or computed tomography (CT) scan; and
- blood tests to measure blood cholesterol, triglycerides, and other substances.

Preparation

The patient should quit **smoking** or using tobacco products before the surgery, and the patient needs to make the commitment to be a nonsmoker after the surgery. There are many smoking cessation programs available through hospital or community groups. A health care provider can provide more information about ways quit smoking.

Coronary artery bypass graft surgery should ideally be postponed for three months after a heart attack. Whenever possible, patients should be medically stable before the surgery. If the patient develops a cold, **fever**, or **sore throat** within a few days before the surgery, he or she should notify the surgeon's office.

During a preoperative appointment, usually scheduled one to two weeks before surgery, the patient will receive information about what to expect during the surgery and the recovery period. The patient will usually meet the cardiologist, anesthesiologist, nurse clinicians, and surgeon during this appointment or just before the procedure.

The evening before the surgery, the patient showers with antiseptic soap provided by the surgeon's office. After midnight, the patient should not eat or drink anything.

The patient is usually admitted to the hospital on the day the surgery is scheduled. The patient should bring a list of current medications, **allergies**, and appropriate medical records upon **admission to the hospital**.

Before the surgery, the patient is given a blood-thinning drug (usually heparin) that helps to prevent **blood clots**. A sedative is given the morning of surgery. The chest and the area from where the graft will be taken are shaved.

Coronary **angiography** will have been previously performed to show the surgeon where the arteries are blocked and where the grafts might best be positioned. Heart monitoring is initiated. The patient is given general anesthesia before the procedure.

The length of the procedure depends upon the number of arteries being bypassed, but it generally takes from three to five hours or sometimes longer.

Aftercare

Recovery in the hospital

The patient recovers in a surgical intensive care unit for one to two days after the surgery. The patient will be connected to chest and breathing tubes, a mechanical ventilator, a heart monitor, and other monitoring equipment. A urinary catheter will be in place to drain urine. The breathing tube and ventilator are usually removed about six hours after surgery, but the other tubes remain in place as long as the patient is in the intensive care unit.

Drugs are prescribed to control pain and infection and to prevent unwanted blood clotting. Daily doses of **aspirin** are started within 6–24 hours after the procedure.

The patient is closely monitored during the recovery period. Vital signs and other parameters such as heart sounds, oxygen, and carbon dioxide levels in arterial blood are checked frequently. The chest tube is checked to ensure that it is draining properly. The patient may be fed intravenously for the first day or two.

Chest physiotherapy is started after the ventilator and breathing tubes are removed. The therapy includes coughing, turning frequently, and taking deep breaths. Sometimes oxygen is delivered via a mask to help loosen and clear secretions from the lungs. Other

exercises will be encouraged to improve the patient's circulation and prevent complications due to prolonged bed rest.

If there are no complications, the patient begins to resume a normal routine on the second day, including eating regular food, sitting up, and walking around a bit. Before being discharged from the hospital, the patient usually spends a few days under observation in a non-surgical unit. During this time, counseling is usually provided on eating right and starting a light **exercise** program to keep the heart healthy. The average hospital stay after coronary artery bypass graft surgery is five to seven days.

Recovery at home

INCISION AND SKIN CARE. The incision should be kept clean and dry. When the skin is healed, the incision should be washed with soapy water. The scar should not be bumped, scratched, or otherwise disturbed. Ointments, lotions, and dressings should not be applied to the incision unless specific instructions have been given to do so.

DISCOMFORT. While the incision scar heals, which takes one to two months, it may be sore. **Itching**, tightness, or numbness along the incision are common. Muscle or incision discomfort may occur in the chest during activity.

Swelling or aching may occur in the legs if the saphenous vein was used for the graft. Special support stockings may be needed to decrease leg swelling after surgery. While sitting, the patient should not cross the legs and the feet should be elevated. Walking daily, even if the legs are swollen, will help improve circulation and reduce swelling.

LIFESTYLE CHANGES. The patient needs to make several lifestyle changes after surgery, including:

- quitting smoking. Smoking causes damage to the bypass grafts and other blood vessels, increases the patient's blood pressure and heart rate, and decreases the amount of oxygen available in the blood.
- managing weight. Maintaining a healthy weight, by watching portion sizes and exercising, is important. Being overweight increases the work of the heart.
- participating in an exercise program. The exercise program is usually tailored for the patient, who will be encouraged to participate in a cardiac rehabilitation program supervised by exercise professionals.
- making dietary changes. Patients should eat a lot of fruits, vegetables, whole grains, and non-fat or low-fat dairy products, and reduce fat intake to less than 30% of all calories.
- taking medications as prescribed. Aspirin and other heart medications may be prescribed, and the patient may need to take these medications for life.
- following up with health care providers. The patient must schedule follow-up visits to determine how effective the surgery was, to confirm that progressive exercise is safe, and to monitor his or her recovery and control risk factors.

Risks

Coronary artery bypass graft surgery is major surgery and patients may experience any of the normal complications associated with major surgery and anesthesia, such as the risk of bleeding, **pneumonia**, or infection. Other possible complications include:

- graft closure or blockage;
- development of blockages in other arteries;
- damage to the aorta;
- long-term development of atherosclerotic disease of saphenous vein grafts;
- abnormal heart rhythms;
- high or low blood pressure;
- recurrence of angina;
- blood clots that can lead to a stroke or heart attack;
- kidney failure;
- depression or severe mood swings; and
- possible short-term memory loss, difficulty thinking clearly, and problems concentrating for long periods (these effects generally subside within six months after surgery).

There is a higher risk for complications in patients who:

- are heavy smokers;
- have a history of lung, kidney, or metabolic diseases;
- have diabetes;
- have had a recent heart attack; or
- have a history of angina, ventricular arrhythmias, congestive heart failure, cerebrovascular disease, or mitral regurgitation.

The risk of death while in the hospital during and after coronary artery bypass graft surgery is 1–2%, although the rate varies among individual hospitals and surgeons. In 5–10% of coronary artery bypass graft surgeries, the bypass graft stops supplying

WWW.BOOKBAZ.IR

blood to the bypassed artery within one year. Younger people who are healthy except for the **heart disease** achieve good results with bypass surgery. Patients who have poorer results from coronary artery bypass graft surgery include those over the age of 70, those who have poor left ventricular function, are undergoing a repeat surgery or other procedures concurrently, and those who continue smoking, do not treat high **cholesterol** or other coronary risk factors, or have another debilitating disease.

Over the long term, symptoms recur in only about 3–4% of patients per year. Five years after coronary artery bypass graft surgery, survival expectancy is 90%, at 10 years it is about 85%, at 15 years it is about 55%, and at 20 years it is about 40%.

Angina recurs in about 40% of patients after 10 years. In most cases, it is less severe than before the surgery and can be controlled with drug therapy. In patients who have had vein grafts, 40% of the grafts are severely obstructed 10 years after the procedure. Repeat coronary artery bypass graft surgery may be necessary, and is usually less successful than the first surgery.

Results

Full recovery from coronary artery bypass graft surgery takes two to three months and is a gradual process. Upon release from the hospital, the patient will feel weak because of the extended bed rest in the hospital. Within a few weeks, the patient should begin to feel stronger.

Most patients are able to drive 3–8 weeks, after receiving approval from their physician. Sexual activity can generally be resumed in three to four weeks, depending on the patient's rate of recovery.

It takes about six to eight weeks for the sternum to heal. During this time, the patient should not perform activities that cause pressure or weight on the breastbone or tension on the arms and chest. Pushing and pulling heavy objects (as in mowing the lawn) should be avoided and lifting objects more than 20 lbs (9 kg) is not permitted. The patient should not hold his or her arms above shoulder level for a long period, such as when doing household chores. The patient should try not to stand in one place for longer than 15 minutes. Stair climbing is permitted unless other instructions have been given. Within four to six weeks, people with sedentary office jobs can return to work. People with physical jobs, such as construction work or jobs requiring heavy lifting, must wait longer (up to 12 weeks) or may have to change careers.

About 90% of patients experience significant improvements after coronary artery bypass graft surgery. Patients experience full relief from chest pain and resume their normal activities in about 70% of the cases; the remaining 20% experience partial relief.

Coronary artery bypass surgery does not prevent coronary artery disease from recurring. For most people, the graft remains open for about 10–15 years. Therefore, lifestyle changes are strongly recommended and medications are prescribed to reduce the risk for the return of coronary artery disease. About 40% of patients have a new blockage within 10 years after surgery and require a second bypass, change in medication, or an interventional procedure.

Alternatives

All patients with coronary artery disease can help improve their condition by making lifestyle changes such as quitting smoking, losing weight if they are overweight, eating healthy foods, reducing blood cholesterol, exercising regularly, and controlling diabetes and high blood pressure.

All patients with coronary artery disease should be prescribed medications to treat their condition. Antiplatelet medications such as aspirin or clopidogrel (Plavix) are usually recommended. Other medications used to treat angina may include **beta blockers**, nitrates, and angiotensin-converting enzyme (ACE) inhibitors. Medications may also be prescribed to lower lipoprotein levels, since elevated lipoprotein levels have been associated with an increased risk of cardiovascular problems.

Treatment with **vitamin E** is not recommended because it does not lower the rate of cardiovascular events in people with coronary artery disease. **Antioxidants** such as vitamin C and beta-carotene show some signs of helping reduce coronary artery disease, but not enough rigorously documented information about their effects is available and they are not recommended for routine use. Treatment with **folic acid** and **vitamins** B_6 and B_{12} lowers **homocysteine** levels (reducing the risk for cardiovascular problems), but more studies are needed to determine if lowered homocysteine levels correlate with a reduced rate of cardiovascular problems in treated patients.

Less invasive, nonsurgical interventional procedures, such as balloon **angioplasty**, stent placement, rotoblation, **atherectomy**, or brachytherapy, can be performed to open a blocked artery. These procedures may be the appropriate treatment for some patients before coronary artery bypass graft surgery is considered.

Enhanced external counterpulsation (EECP) may be a treatment option for patients who are not candidates for interventional procedures or coronary artery bypass graft surgery. During EECP, a set of cuffs is wrapped around the patient's calves, thighs, and buttocks. These cuffs gently but firmly compress the blood vessels in the lower limbs to increase blood flow to the heart. The inflation and deflation of the cuffs are electronically synchronized with the heartbeat and blood pressure using **electrocardiography** and blood pressure monitors. EECP may encourage blood vessels to open small channels to eventually bypass blocked vessels and improve blood flow to the heart. Not all patients are candidates for this procedure, and treatments, lasting one to two hours, must be repeated about five times a week for up to seven weeks.

Coronary artery disease

Definition

Coronary artery disease is a narrowing or blockage of the arteries and vessels that provide oxygen and nutrients to the heart. It is caused by atherosclerosis, an accumulation of fatty materials on the inner linings of arteries. The resulting blockage restricts blood flow to the heart. When the blood flow is completely cut off, the result is a **heart attack**.

Description

Coronary artery disease, also called coronary **heart disease** or heart disease, is the leading cause of death for both men and women in the United States. According to the American Heart Association, deaths from coronary artery disease have declined some since about 1990, but more than 40,000 people still died from the disease in 2000. About 13 million Americans have active symptoms of coronary artery disease.

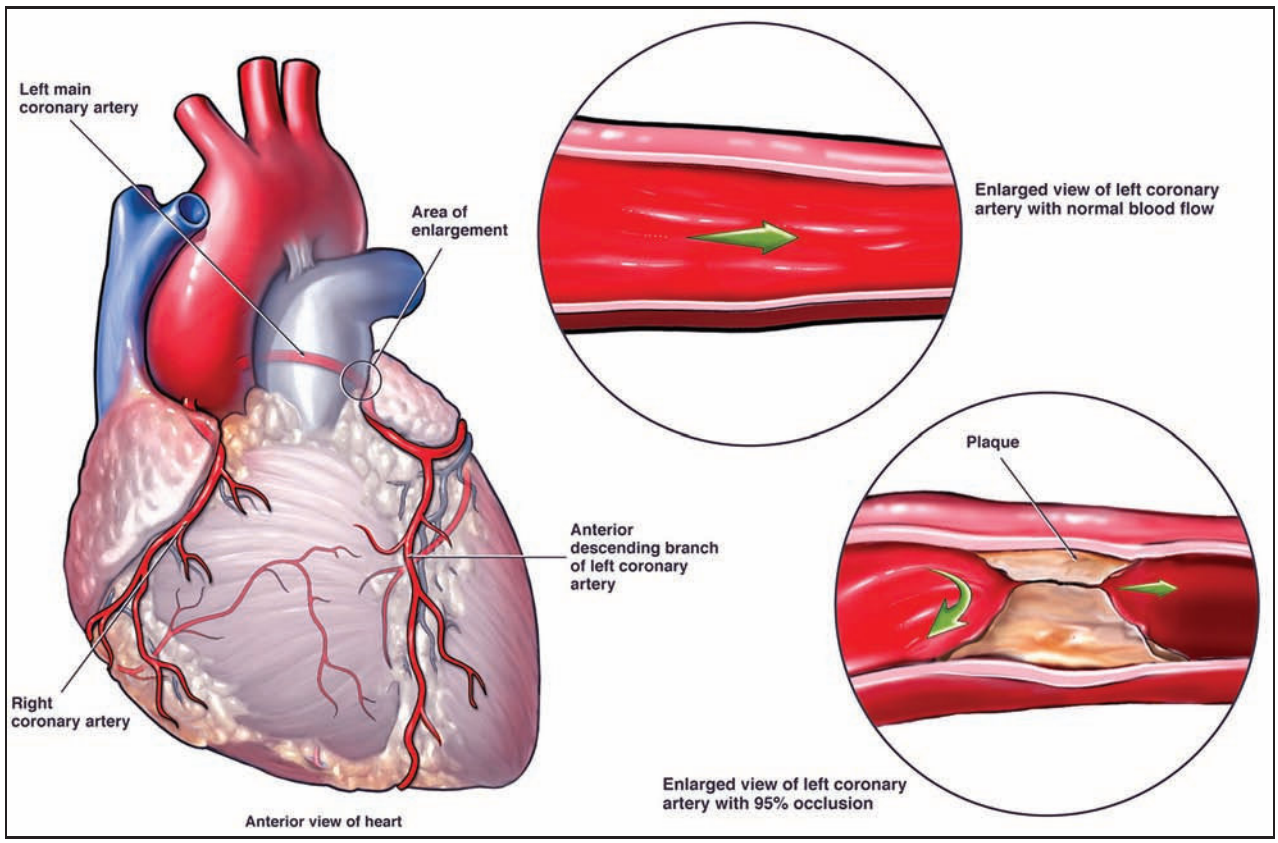
Coronary artery disease occurs when the coronary arteries become partially blocked or clogged. This blockage limits the flow of blood from the coronary arteries, which are the major arteries supplying oxygen-rich blood to the heart. The coronary arteries expand when the heart is working harder and needs more oxygen. Arteries expand, for example, when a person is climbing stairs, exercising, or having sex. If the arteries are unable to expand, the heart is deprived of oxygen (myocardial ischemia). When the blockage is limited, chest **pain** or pressure, called **angina**, may occur. When the blockage cuts off the flow of blood, the result is heart attack (myocardial infarction or heart muscle death).

Healthy coronary arteries are clean, smooth, and slick. The artery walls are flexible and can expand to let more blood through when the heart needs to work harder. The disease process in arteries is thought to begin with an injury to the linings and walls of the arteries. This injury makes them susceptible to atherosclerosis and **blood clots** (thrombosis).

Causes and symptoms

Coronary artery disease is usually caused by atherosclerosis. **Cholesterol** and other fatty substances accumulate on the inner wall of the arteries. They attract fibrous tissue, blood components, and **calcium**, and harden into artery-clogging plaques. Atherosclerotic plaques often form blood clots that also can block the coronary arteries (coronary thrombosis). Congenital defects and **muscle spasms** can also

WWW.BOOKBAZ.IR



Normal blood flow through the coronary artery compared to blood flow blocked by an occlusion. *(© Nucleus Medical Art, Inc./ Alamy.)*

block blood flow. Recent research indicates that infection from organisms such as chlamydia bacteria may be responsible for some cases of coronary artery disease.

A number of major contributing factors increase the risk of developing coronary artery disease. Some of these can be changed and some cannot. People with more risk factors are more likely to develop coronary artery disease.

Major risk factors

Major risk factors significantly increase the chance of developing coronary artery disease. Those that cannot be changed are:

- Heredity—People whose parents have coronary artery disease are more likely to develop it. African Americans also are at increased risk because they experience a higher rate of severe hypertension than whites.
- Sex—Men are more likely to have heart attacks than women and to have them at a younger age. Over age 60, however, women have coronary artery disease at a rate equal to that of men.
- Age—Men who are 45 years of age and older and women who are 55 years of age and older are more likely to have coronary artery disease. Occasionally, coronary disease may strike a person in the 30s. Older people (those over 65) are more likely to die of a heart attack. Older women are twice as likely as older men to die within a few weeks of a heart attack.

Major risk factors that can be changed are:

- Smoking—Smoking increases both the chance of developing coronary artery disease and the chance of dying from it. Smokers are two to four times more likely than are non-smokers to die of sudden heart attack. They are more than twice as likely as non-smokers to have a heart attack. They also are more likely to die within an hour of a heart attack. Second hand smoke also may increase risk.
- High cholesterol—Dietary sources of cholesterol are meat, eggs, and other animal products. The body also produces it. Age, sex, heredity, and diet affect one's blood cholesterol. Total blood cholesterol is

considered high at levels above 240 mg/dL and borderline at 200-239 mg/dL. High-risk levels of low-density lipoprotein (LDL cholesterol) begin at 130-159 mg/dL, depending on other risk factors. Risk of developing coronary artery disease increases steadily as blood cholesterol levels increase above 160 mg/dL. When a person has other risk factors, the risk multiplies.

- High blood pressure—High blood pressure makes the heart work harder and weakens it over time. It increases the risk of heart attack, stroke, kidney failure, and congestive heart failure. A blood pressure of 140 over 90 or above is considered high. As the numbers rise, high blood pressure goes from Stage 1 (mild) to Stage 4 (very severe). In combination with obesity, smoking, high cholesterol, or diabetes, high blood pressure raises the risk of heart attack or stroke several times.
- Lack of physical activity—Lack of exercise increases the risk of coronary artery disease. Even modest physical activity, like walking, is beneficial if done regularly.
- Diabetes mellitus—The risk of developing coronary artery disease is seriously increased for diabetics. More than 80% of diabetics die of some type of heart or blood vessel disease.

Contributing risk factors

Contributing risk factors have been linked to coronary artery disease, but the degree of their significance is not known yet. Contributing risk factors are:

- Hormone replacement therapy–Evidence from a large trial called the Women's Health Initiative released in 2002 and 2003 found that hormone replacement therapy is a risk factor for coronary artery disease in postmenopausal women. The therapy was once thought to help protect women against heart disease, but in the trial, it was discovered that it was harmful to women with existing coronary artery disease.
- Obesity—Excess weight increases the strain on the heart and increases the risk of developing coronary artery disease even if no other risk factors are present. Obesity increases blood pressure and blood cholesterol and can lead to diabetes.
- Stress and anger—Some scientists believe that stress and anger can contribute to the development of coronary artery disease and increase the blood's tendency to form clots (thrombosis). Stress, the mental and physical reaction to life's irritations and challenges, increases the heart rate and blood pressure and can injure the lining of the arteries. Evidence shows that anger increases the risk of dying from heart disease. The risk of heart attack is more than double after an episode of anger.

Chest pain (angina) is the main symptom of coronary heart disease but it is not always present. Other symptoms include **shortness of breath**, and chest heaviness, tightness, pain, a burning sensation, squeezing, or pressure either behind the breastbone or in the arms, neck, or jaws. Many people have no symptoms of coronary artery disease before having a heart attack; 63% of women and 48% of men who died suddenly of coronary artery disease had no previous symptoms of the disease, according to the American Heart Association.

Diagnosis

Diagnosis begins with a visit to the physician, who will take a medical history, discuss symptoms, listen to the heart, and perform basic screening tests. These tests will measure weight, blood pressure, blood lipid levels, and fasting blood glucose levels. Other diagnostic tests include resting and exercise electrocardiogram, **echocardiography**, radionuclide scans, and coronary **angiography**. The treadmill exercise (**stress**) test is an appropriate screening test for those with high risk factors even when they feel well.

An electrocardiogram (ECG) shows the heart's activity and may reveal a lack of oxygen (ischemia). Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. They send impulses of the heart's activity through an oscilloscope (a monitor) to a recorder that traces them on paper. The test takes about 10 minutes and is performed in a physician's office. A definite diagnosis cannot be made from **electrocardiography**. About 50% of patients with significant coronary artery disease have normal resting electrocardiograms. Another type of electrocardiogram, known as the exercise **stress test**, measures how the heart and blood vessels respond to exertion when the patient is exercising on a treadmill or a stationary bike. This test is performed in a physician's office or an exercise laboratory. It takes 15–30 minutes. It is not perfectly accurate. It sometimes gives a normal reading when the patient has a heart problem or an abnormal reading when the patient does not.

If the electrocardiogram reveals a problem or is inconclusive, the next step is exercise echocardiography or nuclear scanning (angiography). Echocardiography, cardiac **ultrasound**, uses sound waves to create an image of the heart's chambers and valves. A technologist applies gel to a hand-held transducer, then

WWW.BOOKBAZ.IR

presses it against the patient's chest. The heart's sound waves are converted into an image that can be displayed on a monitor. It does not reveal the coronary arteries themselves, but can detect abnormalities in heart wall motion caused by coronary disease. Performed in a cardiology outpatient diagnostic laboratory, the test takes 30–60 minutes.

Radionuclide angiography enables physicians to see the blood flow of the coronary arteries. Nuclear scans are performed by injecting a small amount of radiopharmaceutical such as thallium into the bloodstream. A device that uses gamma rays to produce an image of the radioactive material (gamma camera) records pictures of the heart. Radionuclide scans are not dangerous. The radiation exposure is about the same as that in a chest x ray. The tiny amount of radioactive material used disappears from the body in a few days. Radionuclide scans cost about four times as much as exercise stress tests but provide more information.

In radionuclide angiography, a scanning camera passes back and forth over the patient who lies on a table. Radionuclide angiography is usually performed in a hospital's nuclear medicine department and takes 30–60 minutes. Thallium scanning usually is done in conjunction with an exercise stress test. When the stress test is finished, thallium or sestamibi is injected. The patient resumes exercise for one minute to absorb the thallium. For patients who cannot exercise, cardiac blood flow and heart rate may be increased by intravenous dipyridamole (Persantine) or adenosine. Thallium scanning is done twice, immediately after injecting the radiopharmaceutical and again four hours (and maybe 24 hours) later. It is usually performed in a hospital's nuclear medicine department. Each scan takes 30–60 minutes.

Coronary angiography is the most accurate method for making a diagnosis of coronary artery disease, but it also is the most invasive. It is a form of **cardiac catheterization** that shows the heart's chambers, great vessels, and coronary arteries using x-ray technology. During coronary angiography the patient is awake but sedated. ECG electrodes are placed on the patient's chest and an intravenous line is inserted. A local anesthetic is injected into the site where the catheter will be inserted. The cardiologist inserts a catheter into a blood vessel and guides it into the heart. A contrast dye is injected to make the heart visible on x-ray cinematography. Coronary angiography is performed in a cardiac catheterization laboratory either in an outpatient or inpatient surgery unit. It takes from 30 minutes to two hours.

Treatment

Coronary artery disease can be treated many ways. The choice of treatment depends on the severity of the disease. Treatments include lifestyle changes and drug therapy, percutaneous transluminal coronary **angioplasty**, and coronary artery bypass surgery. Coronary artery disease is a chronic disease requiring lifelong care. Angioplasty or bypass surgery is not a cure.

People with less severe coronary artery disease may gain adequate control through lifestyle changes and drug therapy. Many of the lifestyle changes that prevent disease progression—a low-fat, low-cholesterol diet, weight loss if needed, exercise, and not smoking—also help prevent the disease from developing.

Drugs such as nitrates, beta-blockers, and calcium-channel blockers relieve chest pain and complications of coronary artery disease, but they cannot clear blocked arteries. Nitrates (nitroglycerin) improve blood flow to the heart. Beta-blockers (acebutelol, propranolol) reduce the amount of oxygen required by the heart during stress. One type of calcium-channel blocker (verapamil, diltiazem hydrochloride) helps keep the arteries open and reduces blood pressure. **Aspirin** helps prevent blood clots from forming on plaques, reducing the likelihood of a heart attack. Cholesterol-lowering medications are also indicated in most cases.

Percutaneous transluminal coronary angioplasty and bypass surgery are procedures that enter the body (invasive procedures) to improve blood flow in the coronary arteries. Percutaneous transluminal coronary angioplasty, usually called coronary angioplasty, is a non-surgical procedure. A catheter tipped with a balloon is threaded from a blood vessel in the thigh into the blocked artery. The balloon is inflated, compressing the plaque to enlarge the blood vessel and open the blocked artery. The balloon is deflated, and the catheter is removed. Coronary angioplasty is performed in a hospital and generally requires a stay of one or two days. Coronary angioplasty is successful about 90% of the time, but for one-third of patients, the artery narrows again within six months. The procedure can be repeated. It is less invasive and less expensive than coronary artery bypass surgery.

In coronary artery bypass surgery, a healthy artery or vein from an arm, leg, or chest wall is used to build a detour around the coronary artery blockage. The healthy vessel then supplies oxygen-rich blood to the heart. Bypass surgery is major surgery. It is appropriate for those patients with blockages in two or three major coronary arteries, those with severely narrowed

left main coronary arteries, and those who have not responded to other treatments. It is performed in a hospital under general **anesthesia**. A heart-lung machine is used to support the patient while the healthy vein or artery is attached past the blockage to the coronary artery. About 70% of patients who have bypass surgery experience full relief from angina; about 20% experience partial relief. Only about 3–4% of patients per year experience a return of symptoms. Survival rates after bypass surgery decrease over time. At five years after surgery, survival expectancy is 90%; at 10 years about 80%, at 15 years about 55%, and at 20 years about 40%.

Various semi-experimental surgical procedures for unblocking coronary arteries are currently being studied. **Atherectomy** is a procedure in which the surgeon shaves off and removes strips of plaque from the blocked artery. In laser angioplasty, a catheter with a laser tip is inserted into the affected artery to burn or break down the plaque. A metal coil called a stent can be implanted permanently to keep a blocked artery open. Stenting is becoming more common.

Alternatives

Natural therapies may reduce the risk of certain types of heart disease, but once symptoms appear, conventional medical attention is necessary. A healthy diet (including cold-water fish as a source of essential fatty acids) and exercise, important components of conventional prevention and treatment strategies, also are emphasized in alternative approaches to coronary artery disease. Herbal medicine offers a variety of remedies that may have a beneficial effect on coronary artery disease. For example, ginger (*Zingiber officinale*) may help reduce cholesterol. Garlic (*Allium sativum*), ginger, and hot red or chili peppers all are circulatory enhancers that can help prevent blood clots. **Yoga** and other bodywork, massage, relaxation therapies, and talking therapies also may help prevent coronary artery disease and stop, or even reverse, the progression of atherosclerosis. Vitamin and mineral therapy to reduce, reverse, or protect against coronary artery disease include chromium, calcium and magnesium, B-complex **vitamins**, the antioxidant vitamins C and E, selenium, and zinc. **Traditional Chinese medicine** may recommend herbal remedies, massage, **acupuncture**, and dietary modification. However, studies released in 2003 showed that vitamins C and E fell short of claims that they helped narrow blockage caused by coronary artery disease. In fact, high doses of the vitamins should be avoided.

Prognosis

In many cases, coronary artery disease can be successfully treated. Advances in medicine and healthier lifestyles have caused a substantial decline in death rates from coronary artery disease since the mid-1980s. New diagnostic techniques enable doctors to identify and treat coronary artery disease in its earliest stages. New technologies and surgical procedures have extended the lives of many patients who would otherwise have died. Research on coronary artery disease continues.

Prevention

A healthy lifestyle can help prevent coronary artery disease and help keep it from progressing. A heart-healthy lifestyle includes eating right, regular exercise, maintaining a healthy weight, no **smoking**, moderate drinking, no recreational drugs, controlling **hypertension**, and managing stress. **Cardiac rehabilitation** programs are excellent to help prevent recurring coronary problems for people who are at risk and who have had coronary events and procedures.

Eating right

A healthy diet includes a variety of foods that are low in fat, especially saturated fat, low in cholesterol, and high in fiber. It includes plenty of fruits and vegetables, nuts and whole grains, and limited **sodium**. Some foods are low in fat but high in cholesterol and some are low in cholesterol but high in fat. Saturated fat raises cholesterol and, in excessive amounts, increases the amount of the clot-forming proteins in blood. Polyunsaturated and monounsaturated fats are good for the heart. Fat should comprise no more than 30% of total daily calories.

Cholesterol, a waxy substance containing fats, is found in foods such as meat, eggs, and other animal products. It also is produced in the liver. Soluble fiber can help lower cholesterol. Dietary cholesterol should be limited to about 300 mg per day. Many popular lipid-lowering drugs can reduce LDL cholesterol by an average of 25–30% when used with a low-fat, low-cholesterol diet.

Fruits and vegetables are rich in fiber, vitamins, and **minerals**. They are low calorie and nearly fat free. Vitamin C and beta-carotene, found in many fruits and vegetables, keep LDL cholesterol from turning into a form that damages coronary arteries.

Excess sodium can increase the risk of high blood pressure. Many processed foods contain large amounts of sodium. Daily intake should be

WWW.BOOKBAZ.IR

KEY TERMS

Angina—Chest pain that happens when diseased blood vessels restrict the flow of blood to the heart. Angina often is the first symptom of coronary artery disease.

Atherosclerosis—A process in which the walls of the coronary arteries thicken due to the accumulation of plaque in the blood vessels. Atherosclerosis is the cause of coronary artery disease.

Beta-blocker—A drug that blocks some of the effects of fight-or-flight hormone adrenaline (epinephrine and norepinephrine), slowing the heart rate and lowering the blood pressure.

Calcium-channel blocker—A drug that blocks the entry of calcium into the muscle cells of small blood vessels (arterioles) and keeps them from narrowing.

Coronary arteries—The main arteries that provide blood to the heart. The coronary arteries surround the heart like a crown, coming out of the aorta, arching down over the top of the heart, and dividing into two branches. These are the arteries in which coronary artery disease occurs.

HDL cholesterol—High-density lipoprotein cholesterol is a component of cholesterol that helps protect against heart disease. HDL is nicknamed "good" cholesterol.

LDL cholesterol—Low-density lipoprotein cholesterol is the primary cholesterol molecule. High levels of LDL increase the risk of coronary heart disease. LDL is nicknamed "bad" cholesterol.

Plaque—A deposit of fatty and other substances that accumulate in the lining of the artery wall.

Triglyceride—A fat that comes from food or is made from other energy sources in the body. Elevated triglyceride levels contribute to the development of atherosclerosis.

limited to about 2,400 mg, about the amount in a teaspoon of salt.

The "Food Guide" Pyramid developed by the U.S. Departments of Agriculture and Health and Human Services provides easy-to-follow guidelines for daily heart-healthy eating. It recommends 6–11 servings of bread, cereal, rice, and pasta; three to five servings of vegetables; two to four servings of fruit; two to three servings of milk, yogurt, and cheese; and two to three servings of meat, poultry, fish, dry beans, eggs, and nuts. Fats, oils, and sweets should be used sparingly. Canola and olive oil are better for the heart than other cooking oils. Coronary patients should be on a strict diet. The American Heart Association advises a diet rish in fatty fish such as salmon, herring, trout, or sardines. If people cannot eat daily servings of these fish, the association recommends three fish oil capsules per day.

Regular exercise

Aerobic exercise can lower blood pressure, help control weight, and increase HDL ("good") cholesterol. It may keep the blood vessels more flexible. The Centers for Disease Control and Prevention and the American College of Sports Medicine recommend moderate to intense aerobic exercise lasting about 30 minutes four or more times per week for maximum heart health. Three 10-minute exercise periods also are beneficial. Aerobic exercise—activities such as walking, jogging, and cycling—uses the large muscle groups and forces the body to use oxygen more efficiently. It also can include everyday activities such as active gardening, climbing stairs, or brisk housework. People with coronary artery disease or risk factors should consult a doctor before beginning an exercise program.

Maintaining a desirable body weight

About one-fourth of all Americans are overweight and nearly one-tenth are obese, according to the Surgeon General's Report on Nutrition and Health. People who are 20% or more over their ideal body weight have an increased risk of developing coronary artery disease. Losing weight can help reduce total and LDL cholesterol, reduce **triglycerides**, and boost HDL cholesterol. It also may reduce blood pressure. Eating right and exercising are two key components of losing weight.

Avoiding recreational drugs

Smoking has many adverse effects on the heart. It increases the heart rate, constricts major arteries, and can create irregular heartbeats. It raises blood pressure, contributes to the development of plaque, increases the formation of blood clots, and causes blood platelets to cluster and impede blood flow. Heart damage caused by smoking can be repaired by quitting. Even heavy smokers can return to heart

health. Several studies have shown that ex-smokers face the same risk of heart disease as non-smokers within 5 to 10 years after quitting.

Drink in moderation. Modest consumption of alcohol may actually protect against coronary artery disease because alcohol appears to raise levels of HDL cholesterol. The American Heart Association defines moderate consumption as 1 oz of alcohol per day, roughly one cocktail, one 8-oz glass of wine, or two 12-oz glasses of beer. However, even moderate drinking can increase risk factors for heart disease for some people (by raising blood pressure, for example). Excessive drinking always is bad for the heart. It usually raises blood pressure and can poison the heart and cause abnormal heart rhythms or even **heart failure**.

Do not use other recreational drugs. Commonly used recreational drugs, particularly cocaine and "crack," can seriously harm the heart and should never be used.

Seeking treatment for hypertension

High blood pressure, one of the most common and serious risk factors for coronary artery disease, can be controlled completely through lifestyle changes and medication. Moderate hypertension can be controlled by reducing dietary intake of sodium and fat, exercising regularly, managing stress, abstaining from smoking, and drinking alcohol in moderation. People for whom these changes do not work or people with severe hypertension may be helped by many categories of medication.

Managing stress

Everyone experiences stress. Stress sometimes can be avoided and when it is inevitable, it can be controlled. It is particularly important for those at risk for heart disease. A 2003 report showed that middle-aged men with high **anxiety** were less likely to adhere to heart healthy lifestyle practices. Techniques for controlling stress include: taking life more slowly, spending more time with family and friends, thinking positively, getting enough sleep, exercising, and practicing relaxation techniques.

Coronary heart disease *see* **Coronary artery disease**

Coronary stenting

Definition

A coronary stent is an artificial support device used in a coronary artery (artery that supplies blood to the heart) to keep the vessel open.

Description

Coronary stenting usually follows balloon **angioplasty**. In this procedure, a stent is mounted on a balloon catheter. The catheter is fed into the femoral artery in the upper thigh and moved through the blood vessels to the blocked coronary artery. When this catheter is positioned at the location of the blockage in the coronary artery, the tip is slowly inflated to widen that artery. Once widened, the catheter is deflated and withdrawn, but the stent stays behind and acts as a scaffold to hold the artery open.

WWW.BOOKBAZ.IR

KEY TERMS

Balloon angioplasty—The use of an inflatable balloon attached to a catheter to widen an artery that has become narrowed. Inflating the balloon forces the artery open.

Cardiac angiography—A procedure used to visualize blood vessels of the heart. A catheter is used to inject a dye into the vessels; the vessels can then be seen by x ray.

Catheter—A long thin flexible tube that can be inserted into the body; in this case, it is threaded to the heart.

Restenosis—The narrowing of a blood vessel after it has been opened, usually by balloon angioplasty.

Thrombosis—The development of a blood clot in the vessels. This thrombosis may clog a blood vessel and stop the flow of blood.

Restinosis, or re-blockage, of the artery is common. According to some studies, about one-quarter of all bare-metal stents become re-blocked, whereas fewer than 10% of drug-eluting stents develop a re-blockage. (A drug-eluting stent releases a drug to block cell proliferation.) A cardiac **angiography** is done to ascertain that the stent is keeping the artery open.

Purpose

The coronary stent is used to keep coronary arteries expanded, usually following a balloon angioplasty. Balloon angioplasty is used in patients with **coronary artery disease**. In this disease, the blood vessels on the heart become narrowed. When this happens, the blood and oxygen supply is reduced to the heart muscle. The primary cause of coronary artery disease is fat deposits blocking the arteries (atherosclerosis). In many cases, balloon angioplasty is unsuccessful and the vessel closes after the procedure (restenosis). By forming a rigid support, the stent can prevent restenosis and reduce the need for coronary bypass surgery. The stent is usually a stainless steel mesh tube. Since the stent is placed inside an artery, the device comes in various sizes to match the size of the artery. There are two kinds of coronary stents. Bare-metal stents are made of metal mesh only. Drug-eluting stents are coated with a material that contains a drug that is gradually released and helps prevent the artery from re-closing.

Alternatives

Balloon angioplasty and coronary stenting are performed to relieve the symptoms of coronary artery disease. By the time coronary artery disease progresses and requires balloon angioplasty, there is no alternative to balloon angioplasty other than coronary bypass surgery. Coronary bypass surgery carries greater risks and a longer recovery time. However, since coronary artery disease can be related to high fat **diets**, **smoking**, and lack of **exercise**, changes in lifestyle may reduce the risk of developing the disease. Various medications for **cholesterol**, high blood pressure, and diabetes also can help treat or prevent coronary artery disease.

Preparation

Before the stent is inserted, the patient will probably be instructed to take **aspirin** for several days. Aspirin can help decrease the possibility of **blood clots** forming at the stent. Because **anesthesia** will be used during the procedure, the patient should not eat or drink after midnight of the previous day.

Aftercare

Following the procedure, blood thinners (anticoagulants) will be given through a needle in a vein for about 24 hours. The patient should remain flat and still for a while to allow the femoral artery to heal from the insertion of the catheter. Medication to control blood clotting should be taken after the patient is discharged from the hospital. A special diet may also be recommended that is low in **vitamin K** and cholesterol. With time, the patient should begin light exercise such as walking. It is important that no **magnetic resonance imaging** (MRI) tests be given for six months because the magnetic field may move the stent.

Risks

Any foreign object in the body, such as a stent, will increase the risk of thrombosis (blood clotting). Anticlotting drugs are given to prevent this complication and must be taken exactly as prescribed.

As with all surgeries, there is a risk of reaction to the administration of anesthesia and of infection following the procedure.

Although coronary stents greatly reduce the risk of restenosis following balloon angioplasty, there is still some risk that the stented artery may close. Thrombosis, bleeding, and artery damage are also risks.

Corticosteroids

Definition

Corticosteroids are group of natural and synthetic analogues of the hormones secreted by the hypothalamic-anterior pituitary-adrenocortical (HPA) axis, more commonly referred to as the pituitary gland. These include glucocorticoids, which are anti-inflammatory agents with a large number of other functions; mineralocorticoids, which control salt and water balance primarily through action on the kidneys; and corticotropins, which control secretion of hormones by the pituitary gland.

Purpose

Glucocorticoids have multiple effects, and are used for a large number of conditions. They affect glucose utilization, fat metabolism, and bone development, and are potent anti-inflammatory agents. They may be used for replacement of natural hormones in patients with pituitary deficiency (Addison's disease), as well as for a wide number of other conditions including, but not limited to, arthritis, **asthma**, anemia, various cancers, and skin inflammations. Additional uses include inhibition of **nausea and vomiting** after **chemotherapy**, treatment of **septic shock**, treatment of spinal cord injuries, and treatment of hirisutism (excessive hair growth). The choice of drug will vary with the condition. Cortisone and hydrocortisone, which have both glucocorticoid and mineralocorticoid effects, are the drugs of choice for replacement therapy of natural hormone deficiency. Synthetic compounds, which have greater anti-inflammatory effects and less effect on salt and water balance, are usually preferred for other purposes. These compounds include dexamethasone, which is almost exclusively glucocorticoid in its actions, as well as prednisone, prednisolone, betamethasone, trimacinolone, and others. Glucocorticoids are formulated in oral dosage forms, topical creams and ointments, oral and nasal inhalations, rectal foams, and ear and eye drops.

Mineralocorticoids control the retention of **sodium** in the kidneys. In mineralocorticoid deficiency, there is excessive loss of sodium through the kidneys, with resulting water loss. Fludrocortisone (Florinef) is the only drug available for treatment of mineralocorticoid deficiency, and is available only in an oral dosage form.

Corticotropin (ACTH, adrenocorticotropic hormone) stimulates the pituitary gland to release cortisone. A deficiency of corticotropic hormone will have the same effects as a deficiency of cortisone. The hormone, which is available under the brand names Acthar and Actrel, is used for diagnostic testing, to determine the cause of a glucocorticoid deficiency, but is rarely used for replacement therapy since direct administration of glucocorticoids may be easier and offers better control over dosages.

Recommended dosage

The dosage of glucocorticoids varies with the drug, route of administration, condition being treated, and patient. Consult specific references.

Fludrocortisone, for use in replacement therapy, is normally dosed at 0.1 mg/day. Some patients

WWW.BOOKBAZ.IR

KEY TERMS

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Hormone—A substance that is produced in one part of the body, then travels through the bloodstream to another part of the body where it has its effect.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Ointment—A thick, spreadable substance that contains medicine and is meant to be used on the outside of the body.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: controlled human studies have demonstrated no fetal risk. Category B: animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: no adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: evidence of fetal risk, but benefits outweigh risks. Category X: evidence of fetal risk. Risks outweigh any benefits.

require higher doses. It should normally be administered in conjunction with cortisone or hydrocortisone.

ACTH, when used for diagnostic purposes, is given as 10–25 units dissolved in 500 mL of 5% dextrose injection infused IV over eight hours. A long-acting form, which may be used for replacement therapy, is given by subcutaneous (SC) or intramuscular (IM) injection at a dose of 40–80 units every 24–72 hours.

Precautions

Glucocorticoids

The most significant risk associated with administration of glucocorticoids is suppression of natural corticosteroid secretion. When the hormones are administered, they suppress the secretion of ACTH, which in turn reduces the secretion of the natural hormones. The extent of suppression varies with dose, drug potency, duration of treatment, and individual patient response. While suppression is seen primarily with drugs administered systemically, it can also occur with topical drugs such as creams and ointments, or drugs administered by inhalation. Abrupt cessation of corticosteroids may result in acute adrenal crisis (Addisonian crisis) that is marked by **dehydration** with severe **vomiting** and **diarrhea**, **hypotension**, and loss of consciousness. Acute adrenal crisis is potentially fatal.

Chronic overdose of glucocorticoids leads to Cushingoid syndrome, which is clinically identical to Cushing's syndrome and differs only in that in Cushingoid the excessive **steroids** are from drug therapy rather than excessive glandular secretion. Symptoms vary, but most people have upper body **obesity**, rounded face, increased fat around the neck, and thinning arms and legs. In its later stages, this condition leads to weakening of bones and muscles with rib and spinal column **fractures**.

The short term adverse effects of corticosteroids are generally mild, and include **indigestion**, increased appetite, **insomnia**, and nervousness. There are also a very large number of infrequent adverse reactions, the most significant of which is drug-induced **paranoia**. **Delirium**, depression, menstrual irregularity, and increased hair growth are also possible.

Long-term use of topical glucocorticoids can result in thinning of the skin. Oral steroid inhalations may cause fungal overgrowth in the oral cavity. Patients must be instructed to rinse their mouths carefully after each dose. Corticosteroids are **pregnancy** category C. The drugs have caused congenital malformations in animal studies, including **cleft palate**. **Breastfeeding** should be avoided.

Mineralocorticoids

Because fludrocortisone has glucocorticoid activity as well as mineralocorticoid action, the same hazards and precautions apply to fludrocortisone as to the glucocorticoids. Overdose of fludrocortisone may also cause **edema**, **hypertension** and **congestive heart failure**.

Corticotropin has all the same risks as the glucocorticoids. Prolonged use may cause reduced response to the stimulatory effects of corticotropin.

Warnings and contraindications

Use corticosteroids with caution in patients with the following conditions:

• osteoporosis or any other bone disease

- current or past tuberculosis
- glaucoma or cataracts
- infections of any type (virus, bacteria, fungus, amoeba)
- sores in the nose or recent nose surgery (if using nasal spray forms of corticosteroids)
- underactive or overactive thyroid
- liver disease
- stomach or intestine problems
- diabetes
- heart disease
- high blood pressure
- high cholesterol
- kidney disease or kidney stones
- myasthenia gravis
- systemic lupus erythematosus (SLE)
- emotional problems
- skin conditions that cause the skin to be thinner and bruise more easily

Interactions

Corticosteroids have many **drug interactions**. Consult specific references.

Corticosteroids, dermatologic

Definition

Dermatologic **corticosteroids** are anti-inflammatory compounds formulated for application to the skin. They are intended for local effects only and are not meant for internal use.

Purpose

Dermatologic corticosteroids are used to treat skin conditions that involve inflammation, usually marked by redness or **itching**. These include **contact dermatitis**, **atopic dermatitis**, nummular **eczema**, stasis eczema, asteatotic eczema, **lichen planus**, **lichen simplex chronicus**, insect and arthropod bite reactions, and first- and second-degree localized **burns** and sunburns.

In addition, dermatologic corticosteroids may be used together with other drugs to treat the symptoms of other conditions that are marked by inflammation of the skin.

Description

All dermatologic **steroids** are based on the natural hormone hydrocortisone, but most have been subject to chemical modification to increase their effectiveness. While many chemical changes to the original molecule will increase the anti-inflammatory effects, the best known is halogenation, replacing one or more of the carbon atoms in the molecule with an atom of fluorine or, less often, chlorine. This change increases the anti-inflammatory effects of the steroid but also increases the risk of some adverse effects.

Topical steroids are usually classed by their potency, ranging from very high to low potency. The most powerful steroids include clobetasol propionate, diflorasone diacetate, and halobetasol propionate. The high and medium potency group includes

WWW.BOOKBAZ.IR

betamethasone valerate, desoximetasone, fluocininide, halcinonide, and fluandrenolide. Low potency topical steroids include desonide, dexamethasone, fluocinolone acetate, and hydrocortisone.

Topical steroids are particularly affected by their vehicle, which can alter the potency of the product and is particularly important in view of the parts of the body being treated. Lotions are liquid at room temperature and are usually the best choice for application to hairy areas of the body since they can easily reach past the hair. Creams are semi-solid and appropriate for application to most areas. They are usually designed to disappear and leave no sticky residue. This feature makes them appropriate for areas such as the palms of the hands, the face, or areas that are in direct contact with clothing. Ointments are thicker than creams and tend to stay on the skin longer than creams. Pastes are particularly thick ointments, often containing a powder such as zinc oxide, and may be used where a protective effect is needed.

Because of variations in skin thickness, it is essential to match the potency of the steroid with the area being treated. Areas of thick skin may require a very potent steroid in order to penetrate the outer layer of skin. In areas where the skin is thin, a high potency steroid may increase the risk of serious adverse reactions.

Recommended dosage

Most topical steroids are applied twice a day, but applications as frequently as four times a day may be appropriate. In some cases, penetration through the skin may be increased by use of occlusion.

Precautions

Excessive use of topical corticosteroids may lead to systemic side effects. Patients using high potency steroids over large areas of the body for a prolonged period should have adrenal function tests.

Normally, areas covered by steroid creams should not be bandaged, since doing so increases the absorption of the steroid and may lead to increased adverse effects.

Some commercially available formulations of topical corticosteroids contain sulfites that may cause allergic reactions. Allergic reactions to other ingredients in topical formulations are very infrequent but have been reported.

Topical corticosteroids should not be used in patients with markedly impaired circulation since skin ulceration has occurred in these patients following use of the drugs.

Topical corticosteroids should be used with extreme caution in areas where the skin is infected and should never be used in infected areas unless the infection is being appropriately treated.

When used properly, these medicines have not been shown to cause problems in humans. Studies on **birth defects** have not been done in humans. However, studies in animals have shown that topical corticosteroids, when applied to the skin in large amounts or used for a long time, can cause birth defects. Maternal use of topical corticosteroids has not been reported to cause problems in nursing babies when used properly. However, corticosteroids should not be applied to the breasts before nursing.

Side effects

When dermatologic corticosteroids are used properly, adverse effects are very rare. Even so, the following effects have been reported:

- blood-containing blisters on skin
- burning and itching of skin
- increased skin sensitivity (for some brands of betamethasone lotion)
- lack of healing of skin condition
- numbness in fingers
- painful, red, or itchy, pus-containing blisters in hair follicles
- raised, dark red, wart-like spots on skin, especially when used on the face
- skin infection
- thinning of skin with easy bruising

Excessive use, either because of use of an inappropriately potent steroid, prolonged use, or inappropriate use of occlusion has been known to lead to more severe adverse effects. However, these reactions are very rare.

Interactions

When used properly, topical steroids have no **drug interactions** or interactions with foods because they do not reach significant levels in the body. Application of another ointment to the same area at the same time may dilute the corticosteroid ointment and result in lowered effectiveness.

KEY TERMS

Corticosteroids—Any of the steroid hormones produced by the adrenal cortex or their synthetic equivalents.

Dermatitis—A disease in which the skin is red and painful. This condition may have different causes. In contact dermatitis, the redness is a reaction to something touching the skin, such as a fabric dye or a metal. Atopic dermatitis is an intense reddening reaction, associated with allergies.

Eczema—A skin disease that causes redness, itching, and scaly or crusty sores. In asteatotic eczema the skin is dry and scaly. Stasis eczema is caused by reduced blood flow.

Lichen planus—An uncommon disorder involving a recurrent, itchy, inflammatory rash or lesion on the skin or in the mouth. The exact cause is unknown, but the disorder is likely to be related to an allergic or immune reaction. The skin lesions are distinct from other disorders.

Systemic—Affecting the entire body.

Topical—Pertaining to a particular surface area and affecting only the area to which it is applied.

Ulceration—Being eroded away, as by an ulcer.

Corticosteroids, inhaled

Definition

Inhaled **corticosteroids** are glucocorticoids (a class of steroid hormones that are synthesized by the adrenal cortex and have anti-inflammatory activity) formulated to be used in the respiratory tract and lungs.

Purpose

Inhaled corticosteroids are glucocorticoid compounds designed to be applied directly to the tissues of the respiratory tract. There are two types. The intranasal are deposited into the nasal passages and may be used to treat **nasal polyps**, perennial **allergic rhinitis**, seasonal allergic **rhinitis**, and recurrent chronic **sinusitis**.

The second type is used when the **steroids** are designed for deposition further into the respiratory tract. These are used for treatment of chronic **asthma** and prevention of asthmatic attacks.

Because they have anti-inflammatory effects, corticosteroids are invaluable in treatment of asthma and other respiratory conditions which are associated with an allergic reaction. In many cases, the corticosteroids are life saving. But **systemic corticosteroids** affect all parts of the body and may cause very severe adverse effects, particularly with long-term use. These reactions include inhibitions of the adrenal glands and weakening of bones. By administering these drugs by inhalation, it is possible to target the areas that require treatment and reduce the amount of drug that reaches other parts of the body. Some patients may be able to

WWW.BOOKBAZ.IR

do without systemic steroids entirely, while others can reduce their doses of systemic steroids and thereby reduce the risk and severity of unwanted effects.

The drugs used as inhaled steroids are all anti-inflammatory corticosteroids and are very similar to each other in action and use. The way they are formulated, the size of the particles, the design of the inhaler, and whether the drugs are inhaled by the mouth or nose determine how far into the respiratory tract the steroids go. The formulations designed for nasal inhalation are only effective for nasal polyps or rhinitis because the steroid does not penetrate deeply into the respiratory tract. Oral inhalations, containing the same drug but in different particle size and inhaler design, deposit medication deeply into the lungs and are of value in treatment of asthma.

Description

There are eight corticosteroid medications designed for inhalation:

- beclomethasone dipropionate (Qvar, Vanceril, and Beclovent)
- budesonide (Pulmicort)
- flunisolide (AeroBID)
- fluticasone propionate (Flovent)
- triamcinolone acetonide (Azmacort)

Also, there is a combination drug of fluticasone propionate and salmeterol xinafoate (Advair Diskus) available for children over 12 years old. Although the different products vary in potency and duration of action, once dose size and frequency have been adjusted to offer comparable results, there do not appear to be significant differences between the drugs. The design of the inhalers, their ease of use, and the training each patient receives in the proper use of the inhaler may be of greater significance than the drug itself.

Recommended dosage

Although the different products vary in milligram potency, for practical purposes, doses are measured in puffs on the inhaler. For example, beclomethasone will deliver 40 micrograms each time the inhaler is used, while triamcinolone delivers 100 micrograms with each inhalation. However, the effects are essentially equal.

The appropriate dose of inhaled corticosteroids depends on the severity of the case, and in some instances, on what treatment has been used prior to starting inhaled steroid therapy. The doses listed are typical of the inhaled steroids used for asthma therapy but do not represent all possible cases:

- beclomethasone: one to two puffs two times a day
- budesonide: one to two puffs two times a day
- flunisolide: two puffs two times a day
- fluticasone propionate: available in forms that deliver either 50 or 100 micrograms of fluticase in each puff; typical initial dose, 100 micrograms two times a day, representing either one puff of the 100 microgram product or two puffs of the 50 microgram product
- triamcinolone acetonide: two puffs three or four times a day or four puffs twice a day, not to exceed 16 puffs daily

Precautions

Particular care is essential for patients who are transferred from systemic corticosteroids to inhaled steroids. Because the long-term use of oral steroids lowers the output of these compounds from the adrenal gland and normal production does not recur for several months, patients who have their oral doses reduced are at risk of adrenal insufficiency. This condition may become particularly serious in the event of **trauma**, surgery, or infections. While inhaled steroids may provide adequate control of asthma during these periods, the inhaled drugs do not replace the systemic compounds. In the event of **stress** or a severe asthma attack, oral therapy must immediately begin. Regular testing for cortisol levels is essential until the normal levels have been resumed.

For patients who had been on systemic therapy and are being switched to corticosteroid inhalation, the immediate period during which the oral dose is reduced may cause symptoms, including joint or muscle **pain**, tiredness, and depression. Continuous monitoring is required until normal functions have been resumed.

It is essential that patients learn proper use of inhalers. If inhalers are not used properly, the corticosteroids may not reach their intended site of action. Instead, they may be left in the mouth or swallowed and be deposited in the digestive tract. This situation may increase the risk of adverse effects, while reducing the protection from asthmatic attacks.

Inhaled corticosteroids are not for treatment of acute asthmatic attacks or rapid relief of bronchospasm.

Inhaled corticosteroids are designated as **pregnancy** category C. This designation means one of two levels of knowledge concerning the drugs adverse effects. In one instance, studies on animals show adverse fetal effects but there are no controlled studies

KEY TERMS

Adrenal glands—The two glands that are located on top of the kidneys. These glands secrete several hormones, including the glucocorticoids which, among other things, influence the way the immune system works, and the mineralocorticoids, which affect retention of water and sodium.

Glucocorticoid—A class of steroid hormones that are synthesized by the adrenal cortex and have anti-inflammatory activity.

Perennial—Present at all seasons of the year.

Polyp—A small vascular growth on the surface of a mucous membrane.

Respiratory tract—The air passages from the nose to the air sacs of the lungs, including the pharynx, larynx, trachea, and bronchi.

Rhinitis—Inflammation of the mucous membranes of the nose.

on women. In the other instance, no studies on animals and women are not available.

Side effects

It can be difficult to evaluate the side effects of inhaled corticosteroids because many of the reported adverse effects are closely associated with dose reduction or discontinuation of systemic steroids. Not all of the adverse reactions listed have been associated with all of the marketed inhaled steroids, but because of the similarities between these drugs, an adverse reaction reported with one must be considered possible for the others.

The most common severe problem is white patches in the mouth due to localized infection. Additional common side effects are:

- cough
- general aches and pains or general feeling of illness
- greenish-yellow mucus in nose
- headache
- hoarseness or other voice changes
- loss of appetite
- runny, sore, or stuffy nose
- unusual tiredness
- weakness

Very rare but severe adverse effects include:

- blindness, blurred vision, eye pain
- large hives
- bone fractures
- diabetes mellitus (increased hunger, thirst, or urination)
- excess facial hair in women
- fullness or roundness of face, neck, and trunk
- growth reduction in children or adolescents
- heart problems
- high blood pressure
- hives and skin rash
- impotence in males
- lack of menstrual periods
- muscle wasting
- numbness and weakness of hands and feet
- weakness
- swelling of face, lips, or eyelids
- tightness in chest, troubled breathing, or wheezing

Interactions

Because inhaled steroids do not reach therapeutic levels in the blood stream, there are no serious interactions. Ketoconazole (Nizoral), an antifungal agent, has been reported to increase blood levels of budesonide and fluticasone, but it is unclear whether this has any importance when the steroids are administered by inhalation.

Corticosteroids, systemic

Definition

Corticosteroids are a group of drugs chemically related to the hormones produced by the adrenal glands as a response to adrenocorticotropic hormone (ACTH), but excluding the sex hormones that are produced by this gland. The primary adrenal corticosteroids are cortisol and aldosterone. Cortisol is a glucocorticoid, responsible for influencing carbohydrate, fat, and protein metabolism. Aldosterone is a mineralocorticoid, responsible for regulating salt and water balance.

All corticosteroids, both natural ones and those which have been developed synthetically, share a similar chemical structure, which is based on the structure of **cholesterol**.

Purpose

The primary purpose of corticosteroids is replacement of naturally occurring hormones when the adrenal glands do not make enough of the natural hormones. Known as Addison's disease, this deficit is marked by low blood pressure, weight loss, loss of appetite, weakness, and a bronze-like **hyperpigmentation** of the skin. Addison's disease requires both glucocorticoid and mineralocorticoid treatment.

Because the glucocorticoids inhibit some portions of the immune response, they are used in treatment of a large number of diseases. The following list includes some of the established uses of systemic corticosteroids.

- acute, severe allergic reactions
- arthritis, osteoarthritis, rheumatoid arthritis, psoriatic arthritis, and gouty arthritis
- adrenocortical insufficiency
- allergic conjunctivitis
- allergic rhinitis
- anemia
- acquired hemolytic and congenital hypoplastic
- ankylosing spondylitis
- asthma
- beryliosis
- bursitis
- corneal ulcers
- Crohn's disease
- dermatitis (atopic, contact, exfoliative, and seborrheic)
- dermatomyositis
- erythema multiforme
- erythroblastopenia
- herpes zoster of the eye
- hypercalcemia secondary to cancer
- hypersensitivity reactions
- idiopathic thrombocytopenic purpura
- leukemia
- lupus erythematosis
- lymphoma
- multiple myeloma
- multiple sclerosis, acute exacerbations
- mycosis fungoides
- optic neuritis
- pemphigus
- pneumonitis (aspiration)
- rheumatic carditis
- Stevens-Johnson syndrome
- thrombocytopenia
- trichinosis with nerve or heart involvement
- tuberculosis, disseminated and fulminating
- tuberculous meningitis
- ulcerative colitis

Dexamethasone, a related corticosteroid, is widely used to prevent the **nausea and vomiting** associated with cancer therapy.

Glucocorticoid treatment is not a cure for any disease or condition, but it may be used as supportive therapy in addition to other treatments.

Description

Because they both have mineralocorticoid and glucocorticoid effects, cortisone and hydrocortisone are preferred for use in treating adrenal insufficiency. When glucocorticoids are used for their anti-

inflammatory and immunosuppressant properties and their effects on blood and lymphatic systems, synthetic compounds, which have increased glucocorticoid effects and minimal mineralocorticoid effects, are generally preferred.

A number of systemic corticosteroid compounds are commercially available. Although they are generally similar, they vary in their potency, sodium-retaining effects, and duration of action.

Short acting

Cortisone has both glucocorticoid and mineralocorticoid effects. It has the lowest potency of the commercially available corticosteroids and a short duration of action. It is appropriate for replacement therapy in patients with adrenal insufficiency.

Hydrocortisone has both glucocorticoid and mineralocorticoid effects. It is more potent than cortisone and has a somewhat longer duration of action. Although hydrocortisone may be used for its systemic effects, it is most commonly used in skin preparations.

Intermediate acting

Prednisone is probably the most widely used of the systemic **steroids**. It has about half the sodium-retaining effects of hydrocortisone but several times the anti-inflammatory effects. Because of the low level of mineralocorticoid effects, however, prednisone is not suitable for treatment of adrenal insufficiency unless it is used in combination with a mineralocorticoid drug. Prednisolone is very similar to prednisone. In addition to oral dosage form, it is available for subcutaneous, intramuscular, and intravenous injection.

Triamcinolone is slightly more potent than prednisone or prednisolone but has no sodium-retaining effects. It is administered various ways, including inhalation for respiratory problems and as ointments and creams for skin conditions. Methylprednisolone, which is similar to triamcinolone, is most commonly given by injection.

Long acting

Dexamethasone is a very potent glucocorticoid, with no mineralocorticoid activity. It is used in various forms, including tablets, injection, ointments, and eye and eardrops. In cancer treatment, dexamethasone is used both for its corticosteroid properties and as an antinauseant, to help control the side effects of other drugs. Betamethasone is similar to dexamethasone. Although the drug is available for systemic use, it is more commonly used in the form of inhalations and ointments. Other corticosteroids are available but are most often used in inhalation form, for **asthma**, **allergic rhinitis**, or other respiratory conditions.

Recommended dosage

Dosages of corticosteroids must be individualized based on the drug selected, the condition being treated, and the response of the patient. In adrenal insufficiency, a dose equivalent to 25 mg of cortisone or 20 mg of hydrocortisone is normally appropriate. In other conditions, a pharmacologic dose (any dose in excess of the replacement dose) is called for. The equivalent doses of corticosteroids are as follows:

- cortisone: 25 mg
- hydrocortisone: 20 mg
- prednisolone: 5 mg
- prednisone: 5 mg
- methylprednisolone: 4 mg
- triamcinolone: 4 mg
- dexamethason: 0.75 mg
- betamethasone: 0.6 mg

For short-term use, corticosteroids are normally administered in two or three doses each day. In most cases, an initial dose equivalent to 5–60 mg of prednisone per day is appropriate. Usually, a response will be seen within ten days. Once a response has been observed, the dose should be carefully reduced to the lowest dose that will provide adequate control. If no response is seen after a reasonable period of time, an alternative method of treatment should be considered. On rare occasions, patients will respond better to one corticosteroid than to others.

In the case of acute exacerbations of **multiple sclerosis**, doses as high as 200 mg of prednisone or prednisolone for a week followed by 80 mg every other day for one month have been used.

Because administration of corticosteroids reduces the output of cortisone from the adrenal glands, dosing should be designed to minimize the effects of corticosteroid therapy on the adrenal glands. For patients who will be taking corticosteroids for a long time, a single dose of the corticosteroid is taken every other morning. This regimen provides benefits for most conditions, while minimizing many adverse effects of long-term steroid administration, including adrenal suppression and protein breakdown. Although alternate day treatment is the preferred dosing schedule, it is not suited for treatment of **rheumatoid arthritis** or ulcerative **colitis**, for which daily doses are essential. Only the shorter acting corticosteroids such as prednisone or prednisolone should be used for alternate-day dosing.

WWW.BOOKBAZ.IR

When corticosteroid treatment is being discontinued, it is frequently useful to reduce the dose gradually, over several days. Many of these tapering schedules have been described. In one tapering schedule glucocorticoid dosage is reduced by the equivalent of 2.5–5 mg of prednisone every three to seven days until the physiologic dose (e.g., 5 mg of prednisone or prednisolone, 0.75 mg of dexamethasone, or 20 mg of hydrocortisone) is reached. Other schedules may call for slower dose adjustments. The dose may have to be increased if there is a flare-up of the condition being treated while the dose is being reduced. Then, tapering may begin again, but at a slower rate.

Precautions

Because corticosteroids reduce the immune response, they should not be used in patients who have active **fungal infections**. Similarly, patients being treated with corticosteroids should avoid receiving live virus vaccines.

Corticosteroids may mask some signs of infection, and new infections may appear during their use. There may be decreased resistance and inability to localize infection. Any evidence of infection should be treated promptly with appropriate anti-infective therapy.

Corticosteroids may activate latent amebic infections. Therefore, it is recommended that latent or active **amebiasis** be ruled out before starting corticosteroid therapy in any patient who has spent time in the tropics or any patient with unexplained **diarrhea**.

Adequate human reproduction studies have not been done with corticosteroids. Use of these drugs in **pregnancy** or in women of childbearing potential requires that the anticipated benefits be weighed against the possible hazards to the mother and embryo or fetus. Infants born of mothers who have received substantial doses of corticosteroids during pregnancy should be carefully observed for signs of hypoadrenalism.

Corticosteroids have been associated with an increased risk of gastric **ulcers**, and patients are usually advised to take these drugs either with food or a drug which inhibits gastric acid. Those taking high dose steroids or on maintenance therapy should take the medication with meals or a gastric acid blocker to reduce the risk of gastric ulcers. However, these precautions are probably not needed for patients taking low doses for a short period of time.

Side effects

Corticosteroids are generally safe when used for a short period of time with appropriate monitoring. When used for longer periods, the frequency and severity of adverse effects increases dramatically. Many of these effects are the unavoidable results of the normal actions of the steroid drugs and must be considered when people decide on a course of long-term corticosteroid therapy.

Fluid and electrolyte disturbances

Sodium retention, fluid retention, **congestive heart failure** in susceptible patients, potassium loss, **calcium** loss, **hypertension** may result from long-term use.

Muscle and bone

Muscle weakness, loss of muscle mass, **osteoporosis**, compression **fractures** of the spine, aseptic **necrosis** of femoral and humeral heads, pathologic fracture of long bones, and tendon rupture are all possible effects from long-term use.

Gastrointestinal effects

Peptic ulcer with possible perforation and hemorrhage, perforation of the small and large bowel particularly in patients with inflammatory bowel disease, **pancreatitis**, abdominal distention, and ulcerative esophagitis can result from long-term use.

Skin reactions

Impaired wound healing, thin fragile skin, red spots, increased sweating, reduced reactions to skin tests, along with other reactions, including **rashes**, **itching** and swelling can all result from long-term use.

Nerves and central nervous system

Convulsions, increased intracranial pressure with **papilledema** (pseudotumor cerebri) usually after treatment, **dizziness** and loss of balance, **headache**, and emotional disturbances can result from long-term use.

Endocrine gland system

Menstrual irregularities, development of cushingoid state, suppression of growth in children, secondary adrenocortical and pituitary unresponsiveness (particularly in times of **stress**, as in **trauma**, surgery, or illness), decreased carbohydrate tolerance, manifestations of latent **diabetes mellitus**, hyperglycemia, increased requirements for insulin or oral hypoglycemic agents in diabetics, and increased hair growth can result from long-term use.

KEY TERMS

Crohn's disease—A chronic inflammatory disease of unknown cause, involving any part of the gastrointestinal tract from mouth to anus, but commonly involving the large intestine, with scarring and thickening of the bowel wall. Crohn's disease frequently leads to intestinal obstruction and has a high rate of recurrence after treatment.

Erythema multiforme—A type of hypersensitivity (allergic) reaction that occurs in response to medications, infections, or illness. Medications associated with erythema multiforme include sulfonamides, penicillins, barbiturates, and phenytoin. Associated infections include herpes simplex and mycoplasma infections. In severe cases, the condition is called Stevens-Johnson syndrome.

Erythroblastopenia—A deficiency in the cells that create red blood cells. This condition may be severe and life-threatening, but there is a transient form, seen in young children, which resolves spontaneously and does not recur.

Hypercalcemia—An excessive amount of calcium in the blood. The most common cause an excess hormone secretion from the parathyroid gland, but hypercalcemia may also be seen in some cancers (lung, breast, multiple myeloma), as a side effect of some drugs, or from excess calcium in the diet.

Mycosis fungoides—The most common type of cutaneous T-cell lymphoma. This low-grade lymphoma primarily affects the skin. Generally, it has a slow course and often remains confined to the skin. Over time, in about 10% of cases, it can progress to the lymph nodes and internal organs.

Optic neuritis—Inflammation of the optic nerve (cranial nerve II) which connects to the retina of the eye. This variable condition can be present with any of the following symptoms: blurred vision, loss of visual acuity, loss of some or all color vision, complete or partial blindness, and pain behind the eye.

Pemphigus—An autoimmune disorder in which the immune system produces antibodies against specific proteins in the skin and mucous membrane. These antibodies produce a reaction that leads to a separation of skin cells.

Pneumonitis (aspiration)—Inflammation of the lung caused by inhaling a liquid, usually carbon based.

Stevens-Johnson syndrome—A severe form of erythema multiforme in which the systemic symptoms are severe and the lesions extensive, involving multiple body areas, especially the mucous membranes.

Trichinosis—A roundworm infection, usually contracted by eating raw or undercooked meat. Trichinosis is rare in the United States but a common infection in some parts of the world.

Ulcerative colitis—A chronic, episodic, inflammatory disease of the large intestine and rectum characterized by bloody diarrhea.

Eye problems

Cataracts, increased intraocular pressure, **glaucoma**, and bulging eyes can result from long-term use.

Other problems

Hypersensitivity, blood clotting problems, weight gain, increased appetite, nausea, and **hiccups** can result from long-term use.

In addition to these long-term effects, other serious effects have been associated with systemic corticosteroid treatment. The severity and likelihood of adverse effects increases both with dose and duration of treatment. Because of their greater effects on sodium and water, the natural corticosteroids, cortisone, and hydrocortisone are more likely to cause fluid and electrolyte problems than the pure glucocorticoids such as dexamethasone and betamethasone.

Interactions

Drugs that stimulate liver enzymes such as phenobarbital, phenytoin, and rifampin may increase the rate of elimination of corticosteroids and may require increases in corticosteroid dose to achieve the desired response.

Drugs such as troleandomycin and ketoconazole may reduce the rate of metabolism of corticosteroids and decrease the rate of elimination. Therefore, the dose of corticosteroid should be lowered to avoid steroid toxicity.

Corticosteroids may increase the rate of elimination of chronic high dose **aspirin**. This effect could lead to decreased salicylate serum levels or increase the risk of salicylate toxicity when corticosteroid is withdrawn.

The effects of corticosteroid treatment on anticoagulants vary. There have been reports of both increased

WWW.BOOKBAZ.IR

anticoagulant activity and decreased anticoagulant activity. Careful monitoring is essential when corticosteroids are used together with anticoagulants.

Corticotropin test *see* **Adrenocorticotropic hormone test**

Cortisol tests

Definition

This test is a measure of serum cortisol (also known as hydrocortisone), or urine cortisol, (also known as urinary free cortisol), an important hormone produced by a pair of endocrine glands called the adrenal glands.

Purpose

This test is performed on patients who may have malfunctioning adrenal glands. Blood and urine cortisol, together with the determination of adrenocorticotropic hormone (ACTH), are the three most important tests in the investigation of Cushing's syndrome (caused by an overproduction of cortisol) and Addison's disease (caused by the underproduction of cortisol).

Precautions

Increased levels of cortisol are associated with **pregnancy**. Physical and emotional **stress** can also elevate cortisol levels. Drugs that may cause increased levels of cortisol include estrogen, **oral contraceptives**, amphetamines, cortisone, and spironolactone (Aldactone). Drugs that may cause decreased levels include androgens, aminoglutethimide, betamethasone, and other steroid medications, danazol, lithium, levodopa, metyrapone and phenytoin (Dilantin).

Description

Cortisol is a potent hormone known as a glucocorticoid that affects the metabolism of carbohydrates, proteins, and fats, but especially glucose. Cortisol increases blood sugar levels by stimulating the release of glucose from glucose stores in cells. It also acts to inhibit insulin, thus affecting glucose transport into cells.

The hypothalamus (an area of the brain), the pituitary gland (sometimes called the "master gland"), and the adrenal glands coordinate the production of cortisol. After corticotropin-releasing hormone (CRH) is made in the hypothalamus, CRH stimulates the pituitary to produce adrenocorticotropic hormone (ACTH). The production of ACTH in turn stimulates a part of the adrenal glands known as the adrenal cortex to produce cortisol. Rising levels of cortisol act as a negative feedback to curtail further production of CRH and ACTH, thus completing an elaborate feedback mechanism.

KEY TERMS

Addison's disease—A rare disorder in which symptoms are caused by a deficiency of hydrocortisone (cortisol) and aldosterone, two corticosteroid hormones normally produced by a part of the adrenal glands called the adrenal cortex. Symptoms include weakness, tiredness, vague abdominal pain, weight loss, skin pigmentation and low blood pressure.

Adrenal glands—A pair of endocrine glands (glands that secrete hormones directly into the bloodstream) that are located on top of the kidneys.

Adrenocorticotropic hormone (ACTH)—Also called corticotropin, this hormone is produced by the pituitary gland to stimulate the adrenal cortex to release various corticosteroid hormones.

Cushing's syndrome—A hormonal disorder caused by an abnormally high level of corticosteroid hormones that are produced by the adrenal glands. Corticosteroid hormones control the body's use of nutrients and the excretion of salts and water in the urine. Symptoms include high blood sugar levels, a moon face, weight gain, and increased blood pressure.

There are two methods for evaluating cortisol: blood and urine. The most reliable index of cortisol secretion is the 24-hour urine sample collection, but when blood levels are required or requested by the physician, plasma cortisol should be measured in the morning and again in the afternoon. Cortisol levels normally rise and fall during the day in what is called a diurnal variation, so that cortisol is at its highest level between 6–8 a.m. and gradually falls, reaching its lowest point around midnight. One reason for ordering blood cortisol levels versus a 24-hour urine collection is that sometimes the earliest sign of adrenal malfunction is the loss of this diurnal variation, even though the cortisol levels are not yet elevated. For example, individuals with Cushing's syndrome often have upper normal plasma cortisol levels in the morning and exhibit no decline as the day progresses.

Preparation

When testing for cortisol levels through the blood, a blood specimen is usually collected at 8 a.m. and again at 4 p.m. It should be noted that normal values may be transposed in individuals who have worked during the night and slept during the day for long periods of time.

When testing for cortisol level through the urine, a 24-hour urine sample is collected, refrigerated, and sent to the reference laboratory for examination.

Risks

Risks for the blood test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Reference ranges for cortisol vary from laboratory to laboratory but are usually within the following ranges for blood:

- adults (8 a.m.): 6–28 mg/dL; adults (4 p.m.): 2–12 mg/dL
- child one to six years (8 a.m.): 3–21 mg/dL; child one to six years (4 p.m.): 3–10 mg/dL
- newborn: 1/24 mg/dL

Reference ranges for cortisol vary from laboratory to laboratory, but are usually within the following ranges for 24-hour urine collection:

- adult: 10–100 mg/24 hours
- adolescent: 5–55 mg/24 hours
- child: 2–27 mg/24 hours

Abnormal results

Increased levels of cortisol are found in Cushing's syndrome, excess thyroid (**hyperthyroidism**), **obesity**, ACTH-producing tumors, and high levels of stress.

Decreased levels of cortisol are found in Addison's disease, conditions of low thyroid, and **hypopituitarism**, in which pituitary activity is diminished.

Cosmetic dentistry

Definition

Cosmetic dentistry includes a variety of dental treatments aimed at improving the appearance of the teeth.

Purpose

The purpose of cosmetic dentistry is to improve the appearance of the teeth using bleaching, bonding, veneers, reshaping, **orthodontics**, or implants.

Description

Bleaching is done to lighten teeth that are stained or discolored. It entails the use of a bleaching solution applied by a dentist or a gel in a tray that fits over the teeth used at home under a dentist's supervision. Bonding involves applying tooth-colored plastic putty, called composite resin, to the surface of chipped or broken teeth. This resin is also used to fill cavities in front teeth (giving a more natural-looking result) and to fill gaps between teeth. Veneers are thin, porcelain shells that cover the front of the teeth. They can improve the appearance of damaged, discolored, misshapen, or misaligned teeth. Reshaping involves the removal of enamel from a misshapen tooth so that it matches other teeth. Orthodontics uses braces to correct the position of crowded or misaligned teeth. Implants are artificial teeth that are attached directly to the jaw to replace missing teeth.

Preparation

Bleaching involves having a custom-made bleaching tray made by the dentist. This tray is worn at home for several hours each day or night. Teeth slowly become white over a period of one to six weeks. Bleaching can also be done in a dentist's office. A heat- or light-activated bleaching solution is applied to six to eight teeth per visit.

Bonding involves etching the surface of the tooth so composite resin can adhere. The dentist then contours the resin to the right shape, and smooths and polishes the resin after it is hard and dry.

To prepare for the application of a veneer, a thin layer of enamel is removed from the tooth (so that the finished tooth will be flush with surrounding teeth) and an impression of the tooth is taken from which the veneer will be created. Before a veneer is applied, the tooth is etched with an acid solution and an adhesive resin is painted on the tooth. The veneer is then applied, the resin is hardened with a bonding light, and the dentist polishes the veneer.

During cosmetic reshaping, some enamel is removed from the uneven tooth so it more closely matches other teeth.

Orthodontics involves applying braces to the teeth, and wires are threaded through the braces. These wires are adjusted to gradually move the teeth to the desired new positions. Over time, crowded or misaligned teeth are straightened.

Implants are more secure and natural looking than dentures or bridgework, but are much more expensive. First, an anchor for the implant is attached to the jaw bone. This surgery can take several hours. About six months later, after the bone around the anchor has healed, a post is attached to the anchor, and an artificial tooth is attached to the post. The whole process may take about nine months to complete.

Aftercare

Periodic touch-up may be needed to keep the teeth white if the teeth have been bleached or bonded. Also, the resin used in bonded teeth can be chipped by ice, popcorn kernels, or hard candy, requiring repair. Veneered teeth may need to be reveneered after five to 12 years. Once orthodontic braces are removed, regular visits to the orthodontist are advised because teeth can shift position. Implanted teeth require regular dental checkups to ensure that the anchor and post are stable.

Risks

After teeth are bleached, they may darken faster if exposed to staining products such as coffee or tobacco. Some patients experience increased sensitivity to cold while teeth are being bleached, but the sensitivity usually disappears shortly after completion of the treatment.

Bonded teeth, like bleached teeth, may also stain more easily than natural teeth. Bonding materials also chip easily.

Because cosmetic reshaping involves the removal of enamel, the process is irreversible because enamel cannot be replaced once it is removed.

The anchors of implanted teeth can loosen and cause **pain**; regular dental checkups are recommended.

Results

Cosmetic dentistry can improve the appearance of stained, chipped, misshapen, or crowded teeth.

KEY TERMS

Bleaching—Technique used to brighten stained teeth.

Bonding—Rebuilding, reshaping, and covering tooth defects using tooth-colored materials.

Composite resin—Plastic material matching natural tooth color used to replace missing parts of a tooth.

Costochondritis

Definition

Costochondritis is an inflammation and associated tenderness of the cartilage (i.e., the costochondral joints) that attaches the front of the ribs to the breastbone.

Description

Costochondritis causes **pain** in the lower rib area or upper breastbone. Some patients fear they are having a **heart attack**. The most severe pain is usually between the breast and the upper abdomen. The pain may be greater when in sitting or reclining positions. **Stress** may aggravate this condition. Generally the third or fourth ribs are affected. However, any of the seven costochondral junctions may be affected, and more often than not more than one site is involved. The inflammation can involve cartilage areas on both sides of the sternum, but usually is on one side only. Costochondritis should be distinguished from Tietze Syndrome, which is an inflammation involving the same area of the chest, but also includes swelling.

Causes and symptoms

The causes of costochondritis are not well-understood and may be difficult to establish. The most likely causes include injury, repetitive minor **trauma**, and unusual excessive physical activity.

The primary symptom of costochondritis is severe chest wall pain, which may vary in intensity. The pain becomes worse with trunk movement, deep breathing, and/or exertion, and better with decreased movement, quiet breathing, or changing of position. It is usually localized but may radiate extensively from the chest area. The pain has been described as sharp, nagging, aching, or pressure-like.

Diagnosis

Diagnosis is based on pain upon palpation (gentle pressing) of the affected joints. Swelling is not associated with costochondritis. Diagnosis is also dependent on the exclusion of other causes, including heart attack or bacterial or **fungal infections** found in IV drug users or postoperative **thoracic surgery** patients.

Treatment

The goals of treatment are to reduce inflammation and to control pain. To accomplish these goals, nonsteroidal anti-inflammatory agents (NSAIDs) are used, with ibuprofen usually selected as the drug of choice. Other NSAIDS options are flurbiprofen, mefenamic acid, ketoprofen, and naproxen. Additional treatment recommendations include the use of local heat, **biofeedback**, and gentle stretching of the pectoralis muscles two to three times a day.

For more difficult cases, where the patient continues to exhibit pain and discomfort, cortisone injections are used as therapy.

Alternatives

Supplements that are used to reduce inflammation have been used to treat costochondritis. Examples of such supplements include ginger root, evening primrose oil, bromelain, **vitamin E**, omega-3 oils, and white willow bark. Glucosamine/chondroitin sulfate, which may aid in the healing of cartilage, has also been used. Other alternative therapies include **acupuncture** and massages.

Prognosis

The prognosis for recovery from costochondritis is good. For most patients, the condition lessens in six months to a year. However, after one year, about one-

WWW.BOOKBAZ.IR

KEY TERMS

Inflammation—Process whereby the immune system reacts to infection or other stimulus, characterized by pain, swelling, redness, and warmth of the affected part

half of patients continue with some discomfort, while about one-third still report tenderness with palpation.

Prevention

Though the causes of costochondritis are not well known, avoidance of activities that may strain (e.g., the repetitive misuse of muscles) or cause trauma to the rib cage is recommended to prevent the occurrence of costochondritis. Modification of improper posture or ergonomics of the home or work place may also deter the development of this condition.

Cough

Definition

A cough is a forceful release of air from the lungs that can be heard. Coughing helps to protect the respiratory system by clearing it of irritants and secretions.

Demographics

Forty percent of Americans are estimated to experience a chronic cough, defined as a cough that persists for at least eight weeks, at some point during their lives.

Description

While people can generally cough voluntarily, a cough is usually a reflex triggered when an irritant stimulates one or more of the cough receptors found at different points in the respiratory system. These receptors then send a message to the cough center in the brain, which in turn tells the body to cough. A cough begins with a deep breath in, at which point the opening between the vocal cords at the upper part of the larynx (glottis) shuts, trapping the air in the lungs. As the diaphragm and other muscles involved in breathing press against the lungs, the glottis suddenly opens, producing an explosive outflow of air at speeds greater than 100 mi (160 km) per hour.

In normal situations, most people cough once or twice an hour during the day to clear the airway of irritants. However, when the level of irritants in the air is high or when the respiratory system becomes infected, coughing may become frequent and prolonged. It may interfere with **exercise** or sleep, and it may cause distress if accompanied by **dizziness**, chest **pain**, or breathlessness. In the majority cases, frequent coughing lasts one to two weeks and tapers off as the irritant or infection subsides. If a cough lasts more than eight weeks, it is considered a chronic cough, and physicians will try to determine a cause beyond an acute infection or irritant.

Coughs are generally described as either dry or productive. A dry cough does not bring up a mixture of mucus, irritants, and other substances from the lungs (sputum), while a productive cough does. In the case of a bacterial infection, the sputum brought up in a productive cough may be greenish, gray, or brown. In the case of an allergy or viral infection it may be clear or white. In the most serious conditions, the sputum may contain blood.

Causes and symptoms

In the majority of cases, coughs are caused by respiratory infections, including:

- colds or influenza, the most common causes of coughs
- bronchitis, an inflammation of the mucous membranes of the bronchial tubes
- croup, a viral inflammation of the larynx, windpipe, and bronchial passages that produces a bark-like cough in children
- whooping cough, a bacterial infection accompanied by the high-pitched cough for which it is named
- pneumonia, a potentially serious bacterial infection that produces discolored or bloody mucus

- tuberculosis, another serious bacterial infection that produces bloody sputum
- fungal infections, such as aspergillosis, histoplasmosis, and cryptococcoses

Environmental pollutants, such as cigarette smoke, dust, or smog, can also cause a cough. In the case of cigarette smokers, the nicotine present in the smoke paralyzes the hairs (cilia) that regularly flush mucus from the respiratory system. The mucus then builds up, forcing the body to remove it by coughing. Post-nasal drip, the irritating trickle of mucus from the nasal passages into the throat caused by **allergies** or **sinusitis**, can also result in a cough. Some chronic conditions, such as **asthma**, chronic **bronchitis**, **emphysema**, and **cystic fibrosis**, are characterized in part by a cough. A condition in which stomach acid backs up into the esophagus (gastroesophageal reflux) can cause coughing, especially when a person is lying down. A cough can also be a side effect of medications that are administered via an inhaler. It can also be a side-effect of beta-blockers and ACE inhibitors, which are drugs used for treating high blood pressure.

Diagnosis

Examination

To determine the cause of a cough, a physician should take an exact medical history and perform an exam. Information regarding the duration of the cough, other symptoms may accompany it, and environmental factors that may influence it aid the doctor in his or her diagnosis. The appearance of the sputum will also help determine what type of infection, if any, may be involved. The doctor may even observe the sputum microscopically for the presence of bacteria and white blood cells.

Tests

Chest x rays may help indicate the presence and extent of such infections as **pneumonia** or **tuberculosis**. If these actions are not enough to determine the cause of the cough, a **bronchoscopy** or **laryngoscopy** may be ordered. These tests use slender tubular instruments to inspect the interior of the bronchi and larynx.

Treatment

Drugs

Treatment of a cough generally involves addressing the condition causing it. An acute infection such as pneumonia may require **antibiotics**, an asthma-induced cough may be treated with the use of **bronchodilators**, or an antihistamine may be administered in the case of an allergy. Physicians prefer not to suppress a productive cough, since it aids the body in clearing the respiratory system of infective agents and irritants. However, cough medicines may be given if the patient cannot rest because of the cough or if the cough is not productive, as is the case with most coughs associated with colds or flu. The two types of drugs used to treat coughs are antitussives and **expectorants**.

ANTITUSSIVES. Antitussives are drugs that suppress a cough. Narcotics—primarily codeine—are used as antitussives and work by depressing the cough center in the brain. They can cause such side effects as drowsiness, nausea, and **constipation**. Dextromethorphan, the primary ingredient in many over-the-counter cough remedies, also depresses the brain's cough center, but without the side effects associated with **narcotics**. Demulcents relieve coughing by coating irritated passageways.

EXPECTORANTS. Expectorants are drugs that make mucus easier to cough up by thinning it. Guaifenesin and terpin hydrate are the primary ingredients in most over-the-counter expectorants. However, some studies have shown that in acute infections, simply increasing fluid intake has the same thinning effect as taking expectorants.

Alternatives

Coughs due to bacterial or viral upper respiratory infections may be effectively treated with botanical and homeopathic therapies. The choice of remedy will vary and be specific to the type of cough the patient has. Some combination over-the-counter herbal and homeopathic cough formulas can be very effective for cough relief. Lingering coughs or coughing up blood should be treated by a trained practitioner.

Many health practitioners advise increasing fluids and breathing in warm, humidified air as ways of loosening chest congestion. Others recommend hot tea flavored with honey as a temporary home remedy for coughs caused by colds or flu. Various **vitamins**, such as vitamin C, may be helpful in preventing or treating conditions (including colds and flu) that lead to coughs. Avoiding mucous-producing foods can be effective in healing a cough condition. These mucous-producing foods vary, based on individual intolerance, but dairy products are a major mucous-producing food for most people.

Prognosis

Because the majority of coughs are related to the **common cold** or **influenza**, most will end in seven to

WWW.BOOKBAZ.IR

KEY TERMS

Antitussives—Drugs used to suppress coughing.

Expectorant—Drug used to thin mucus.

Gastroesophageal reflux—Condition in which stomach acid backs up into the esophagus.

Glottis—The opening between the vocal cords at the upper part of the larynx.

Larynx—A part of the respiratory tract between the pharynx and the trachea, having walls of cartilage and muscle and containing the vocal cords.

Sputum—The mixture of mucus, irritants, and other substances expelled from the lungs by coughing.

21 days. The outcome of coughs due to a more serious underlying disease depends on the pathology of that disease.

Prevention

It is important to identify and treat the underlying disease and origin of the cough. Avoiding **smoking** and direct contact with people experiencing cold or flu symptoms is recommended. Washing hands frequently during episodes of upper-respiratory illnesses is advised. Parents should follow recommended **vaccination** schedules for pertussis (whooping cough) to help prevent the disease from occurring.

Cough suppressants

Definition

Cough suppressants, antitussives, are medicines that reduce or prevent coughing.

Purpose

These medicines are meant to be used to relieve dry, hacking coughs associated with minor conditions like colds and flu. They should not be used to treat coughs associated with coughs that are productive of phlegm or sputum, or from **smoking** or chronic lung conditions like **asthma** or **emphysema**.

Description

Benzonatate (Tessalon) is chemically related to local anesthetics and comes in liquid-filled capsules that are available only by prescription.

Codeine and hydrocodone are opoid drugs that are combined in cough medicines used to suppress coughs. They are available only by prescription

Dextromethorphan is available in over-the-counter cough preparations as liquids, capsules, liquid-filled capsules, lozenges and tablets.

Recommended dosage

Consult with prescribers or pharmacists regarding dose of prescription cough suppressant medications.

Tessalon is usually taken in 100 mg capsules every four hours or three times daily.

Read labels on over-the-counter dextramethorphan cough suppressant medications.

Precautions

Because of fears of overdose, dextromethorphan products should not be given to children under four years of age.

KEY TERMS

Asthma—A disease in which the air passages of the lungs become inflamed, narrowed, and irritable.

Chronic—A word used to describe a long-lasting condition. Chronic conditions often develop gradually and involve slow changes.

Emphysema—An irreversible lung disease in which breathing becomes increasingly more difficult.

Mucus and phlegm—Thick fluid produced by the moist membranes that line breathing passages.

Phenylketonuria (PKU)—A genetic disorder in which the body lacks an important enzyme. If untreated, the disorder can lead to brain damage and intellectual disabilities (ID).

Do not take more than the recommended daily dosage of cough suppressants.

A lingering cough could be a sign of a more serious medical condition. Coughs that last more than seven days or are associated with **fever**, rash, **sore throat**, or lasting **headache** should have medical attention.

People with **phenylketonuria** should be aware that some cough suppressant products contain the artificial sweetener aspartame, which breaks down in the body to phenylalanine.

All cough suppressants can produce or accentuate drowsiness associated with other medicines.

Anyone who has asthma or **liver disease** should check with a physician before taking dextromethorphan.

Women who are pregnant or **breastfeeding** or who plan to become pregnant should check with their physicians before taking dextromethorphan.

The dye tartrazine is an ingredient in some cough suppressant products. This dye causes allergic reactions in some people, especially those who are allergic to **aspirin**.

Side effects

Side effects may include drowsiness, **dizziness**, upset stomach or **nausea and vomiting**.

Interactions

Taking dextromethorphan and **monoamine oxidase inhibitors** (MAOI) (Nardil, Marplan and Parnate) together can be deadly. The effects of MAOI last for up to two weeks after stopping the drugs.

Combining dextromethorphan and sibutramine (Meridia) can produce irritability, weakness and altered consciousness.

All cough suppressants can accentuate the sedative effects of sedative and tranquilizing medicines.

Couvade syndrome

Definition

Couvade syndrome, which is also known as sympathetic **pregnancy**, male pregnancy experience, or "pregnant dad syndrome," refers to a condition in which a father-to-be experiences some of the physical symptoms of pregnancy prior to the baby s birth. The term *couvade* comes from the French verb *couver*, meaning "to brood," in the sense of a bird protecting its eggs before they hatch.

Description

The term couvade was first used by the anthropologist E. B. Tylor in 1865 to describe certain fatherhood rituals performed by husbands while their wives were giving birth. These rituals were found in many different historical periods as well as various cultures around the world, ranging from ancient Greece and parts of the Roman Empire to Chinese Turkestan, the Basque regions of northern Spain, China, Thailand, Borneo, parts of Russia, and many Indian tribes in North as well as South America. In some cultures the expectant father avoids eating certain foods or handling knives or other sharp tools while the mother is in labor. In Papua New Guinea the father builds a hut apart from the rest of the village and goes to bed when his wife s **childbirth** begins. He then stays in bed and imitates the pains of childbirth until the baby is born. A similar custom is observed among the Basques. Couvade rituals are thought to have a number of possible purposes, depending on the specific culture:

- To draw the attention of evil spirits away from the mother to the father instead.

WWW.BOOKBAZ.IR

- To strengthen the emotional bond between father and child.
- To show that the man is the child's biological father.
- To relieve the father's anxiety while the mother is in labor.
- To strengthen the father's relationship with supernatural beings so that he can guide the child into the world.

Ritual couvade is no longer observed in most developed countries, but the term couvade syndrome has been applied to the physical symptoms that many men in these countries experience during a wife's pregnancy, ranging from mild nausea or backaches to weight gain or **toothache**. One group of Italian researchers reported that the number of men who experience couvade syndrome ranges between 11% and 65%, while others estimate that as many as 80% of expectant fathers develop these symptoms. It is thought that more men in Western societies experience couvade syndrome in the early 2000s than was the case with previous generations of fathers, due in part to changes in men s involvement with the birthing process. Some doctors think that the participation of fathers in the delivery room as "coaches" or comforters is one reason for the increased number of men who develop pregnancy symptoms.

Causes and symptoms

Causes

Several different types of explanation have been proposed for couvade syndrome:

- It is a psychiatric disorder. This type of explanation is more common among European than American physicians. Some attribute the symptoms of couvade syndrome to jealousy of the woman s ability to give birth, while others maintain that they result from male guilt over impregnating the woman or to sibling rivalry—that is, the husband regards the wife as a competitor that he must try to outperform.
- It results from real biological changes in the expectant father s body. A team of Canadian researchers reported that their sample of expectant fathers had higher levels of estradiol (a female hormone) and lower levels of testosterone (a male sex hormone) in their blood and saliva than a control group of childless men. The researchers have cautioned, however, that their findings should be checked by studying groups of men from other cultures.
- It is a reaction to a changed social role; that is, the syndrome is one way that some men "work through" their feelings about assuming the social expectations and responsibilities associated with fatherhood.
- It is a set of psychosomatic symptoms that is within the range of normal experience and does not indicate mental illness. Psychosomatic refers to physical symptoms that are caused or influenced by emotional factors, such as stress headaches or "butterflies in the stomach" before an examination.

Symptoms

Expectant fathers may experience one or more of the following:

- weight gain
- nausea and vomiting
- stomach cramps
- constipation or diarrhea
- loss of appetite
- sleep disturbances
- food cravings
- headaches
- toothache
- nosebleeds
- itchy skin

Only a few men, however, develop the more dramatic symptoms. Some studies report that couvade syndrome is most severe during the third or fourth month of the wife s pregnancy and again just before birth. Some researchers report that the syndrome is more common in first-time fathers, while others have found that it is equally likely to develop in men who already have children.

Diagnosis

Couvade syndrome is not listed as a diagnostic category in the most recent editions of the American *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (2000) or the World Health Organization's *International Classification of Diseases*, version 10 (1993). In addition, it is not described or discussed in most medical textbooks, although a few handbooks for doctors in family practice mention it in passing as a condition of unknown origin. Since most men with couvade syndrome have only mild symptoms, they are unlikely to consult a doctor about the condition by itself.

Treatment

There is no standard mainstream treatment recommended for couvade syndrome because it is not usually mentioned in medical textbooks. Anecdotal evidence, however, indicates that most fathers-to-be are helped by a simple explanation of the syndrome

KEY TERMS

Anthropology—The study of the origins, biological characteristics, beliefs, and social customs of human beings.

Psychosomatic—Referring to physical symptoms that are caused or significantly influenced by emotional factors. Some doctors regard couvade syndrome as a psychosomatic condition.

Syndrome—A set of symptoms that occur together.

and reassurance that it is not uncommon among American and Canadian men.

Alternatives

Some expectant fathers report that **meditation** or such movement therapies as **yoga** and t'ai chi are calming and relaxing. Peppermint tea or ginger are herbal remedies that help to relieve nausea.

Prognosis

Couvade syndrome almost always goes away after the baby is born. While a few instances of the syndrome developing into full-blown **psychosis** (loss of contact with reality) have been reported in European medical journals, such cases are extremely rare.

Prevention

There is no known way to prevent couvade syndrome as doctors do not yet understand why some men develop it and others do not.

Rebecca Frey, PhD

Cox-2 inhibitors

Definition

Cox-2 inhibitors are **nonsteroidal anti-inflammatory drugs** (NSAIDs) that are used to relieve **pain** and reduce inflammation.

Purpose

By blocking the Cox-2 enzyme in the intestine, these drugs were expected to lower the risk of **ulcers** that is inherent in using most other NSAIDS, while relieving pain and inflammation.

Description

Celecoxib (Celebrex) is the only available Cox-2 inhibitor drug.

Celecoxib is used to treat rheumatoid and **osteoarthritis**, acute pain, and the pain associated with primary **dysmenorrhea**. In the United States, but not Canada, the drug is also approved to reduce the number of **intestinal polyps** in familial adenomatous polyposis (FAP).

Recommended dosage

For osteoarthritis, the usual dose is 200 mg/day administered as a single dose or as 100 mg twice/day.

For **rheumatoid arthritis**: 100–200 mg twice/day.

Acute pain and primary dysmenorrhea: 400 mg initially, followed by an additional 200 mg dose if needed on the first day. On subsequent days, the recommended dose is 200 mg twice daily as needed.

Precautions

Celebrex is chemically related to sulfa drugs and should not be used by patients with sulfa allergy.

This drug should not be used to treat post-operative pain in patients who have had **coronary artery bypass graft surgery** (CABG).

Celebrex should not be used by patients who have had sensitivity reactions to **aspirin** or other NSAIDS.

This drug should not be used in patients who have aspirin-associated **asthma**.

Celebrex should not be used late in **pregnancy** as it may cause heart problems for newborn babies.

This drug may aggravate active peptic ulcers, liver, kidney and/or heart diseases and intestinal bleeding.

WWW.BOOKBAZ.IR

Side effects

The most common side effects of Celebrex include:

- high blood pressure
- headache
- upset stomach, abdominal pain, diarrhea, gas or bloating
- rash and sometimes more serious skin conditions
- fatigue
- swelling of the feet and legs
- severe allergic reaction, including swelling of the face, throat, tongue, lips, eyes, hoarseness and difficulty swallowing, or breathing

Interactions

Because of its large number of possible side/adverse effects, the effects of other drugs may make it difficult to tell with certainty which adverse effects come from which drug. Drugs that Celebrex can interact with include:

- Taking aspirin and other NSAIDS with Celebrex increases the risk of ulcers and intestinal bleeding.
- Celebrex increases the blood thinning effects of warfarin (Coumadin).
- Celebrex increases the blood thinning effects of the injectable anticoagulants heparin, enoxaparin (Lovenox) and Dalteparin (Fragmin).
- Fluconazole (Diflucan) may increase the blood levels, and possibility of adverse effects, of Celebrex.
- Celebrex increases the blood levels, and possibility of toxicity of lithium (Eskalith).

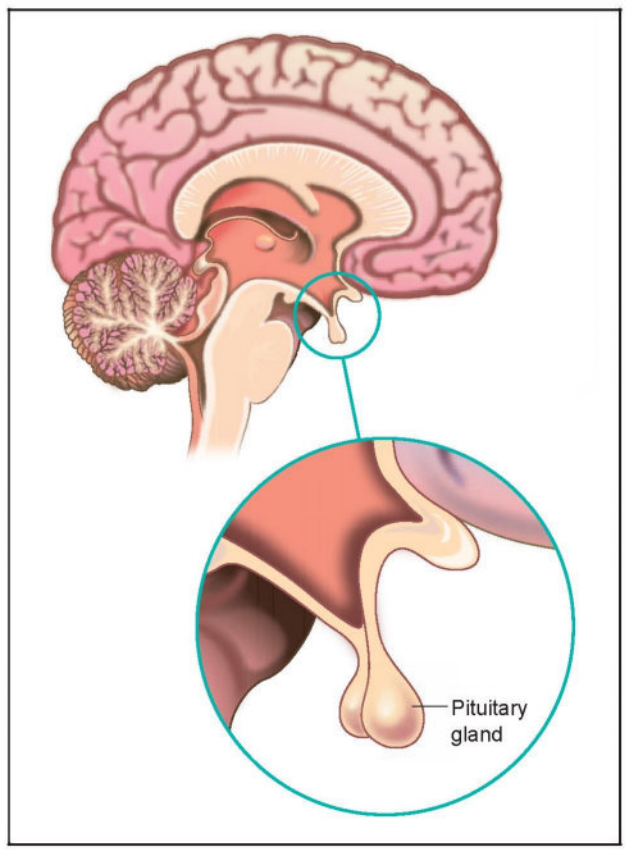
Craniopharyngioma

Definition

Craniopharyngiomas are benign tumors that affect the central nervous system. This type of **brain tumor** is diagnosed primarily in children but can occur at any age.



Craniopharyngiomas are a type of benign brain tumors that affect the functioning of the pituitary gland, which regulates the other endocrine glands in the body. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Demographics

Craniopharyngiomas are a rare type of benign brain tumor. Approximately 300 new cases of craniopharyngioma are diagnosed in the United States each year. Higher incidence rates of craniopharyngioma have been reported in Asia, Africa and Japan.

About 100 of the 300 new cases that occur in the United States each year occur in children ages 0–14 years. One incidence peak of craniopharyngioma occurs between the ages of 5–14. A second incidence peak has been noted in individuals ages 50–74 years.

Description

Craniopharyngiomas develop from embryonic squamous cells located along the craniopharyngeal duct. These tumors frequently occur near critical structures in the brain and can grow to be quite large. As they grow in size they can impair vision, obstruct the flow of cerebrospinal fluid and can affect the normal functioning of the pituitary gland and the hypothalamus which can result in serious complications. Although the tumors are classified as benign tumors, they have a propensity to recur even after treatment. Because of their typical locations near vital structures, treatment is often associated with significant morbidity.

Differences have been noted between craniopharyngiomas that occur in children and adults. Craniopharyngiomas affecting pediatric patients is predominantly of the adamantinomatous cell type. The squamous papillary variant is diagnosed more frequently in adults.

Risk factors

Currently, there are no risk factors identified related to the development of craniopharyngioma.

Causes and symptoms

At this time the cause of craniopharyngioma is unknown. Craniopharygiomas that occur in pediatric patients are thought to arise from the remnants of an embryonic structure that forms a portion of the pituitary gland. These cellular remnants transform into a benign tumor by a process that is not yet fully understood. Researchers believe that a defect in the beta–catenin pathway at the cellular level may contribute to the development of craniopharyngioma. Beta-catenin is a component of the Wnt pathway which has a role in the regulation of cell development, cell differentiation, and cell growth.

The location of craniopharyngiomas in the brain leads to a variety of symptoms resulting from compression of adjacent structures by the tumor. Symptoms associated with craniopharyngiomas include:

- Headache, a common presenting symptom, is present in up to 80% of cases and is a result of increasing intracranial pressure.
- Vomiting, which is often projectile in nature, commonly accompanies headaches in children. Projectile vomiting is also an indicator of increased intracranial pressure.
- Vision loss is another common symptom present at time of diagnosis. Vision loss varies in terms of pattern and severity of loss and ranges from blurred vision to complete visual field loss.
- Symptoms of growth hormone deficiency are present in up to 95% of cases. The most common clinical presentation is short stature.
- Symptoms of hypothyroidism including weight gain, tiredness and fatigue, dry skin and hair, intolerance to cold, anorexia and other related symptoms are often evident.
- Delayed puberty, which may occur in up to 100% of adolescents diagnosed with craniopharyngioma, is a common symptom.
- Mental changes, including seizures, are more commonly seen in adults but are rarely observed in children with craniopharyngioma.

Diagnosis

Examination

A thorough history will be elicited and a comprehensive **physical examination** will be conducted. The clinician's examination will focus on the presenting neurologic and endocrine signs and symptoms. The examination will include checks for **papilledema** and visual field problems which result from increased intracranial pressure. The clinician will also determine whether there is an enlarged head circumference. This finding combined with the presence of papilledema is highly suggestive of a mass within the brain.

The physician will also examine the child to determine whether growth has been compromised. Short stature and stunted growth that is not appropriate for age is a result of endocrine dysfunction and is commonly associated with craniopharyngioma.

Tests

Lab testing indicated for patients with craniopharyngioma includes testing to determine serum electrolyte levels, which may be impaired as a result of

WWW.BOOKBAZ.IR

KEY TERMS

Hypothalmus—An area of the brain located below the thalmus that regulates important functions such as body temperature, hunger and thirst.

Hypothyroidism—Insufficient production of thyroid hormone often resulting from an underactive thyroid gland. Can usually be treated with synthetic hormone replacement therapy.

Increased intracranial pressure—A rise in the normal pressure levels inside the brain.

Intracavitary—Inside a space or cavity within the body.

Morbidity—Adverse effects of treatment; a diseased condition or state; caused by disease; incidence of a particular disease.

Papilledema—Swelling that occurs at the level of the optic nerve. Presence of papilledema is indicative of increased intracranial pressure.

Pituitary gland—Often referred to as the master gland within the endocrine system. Produces hormones that control the functions of other glands within the endocrine system. Controls many body functions especially growth.

Projectile vomiting—Vomiting that occurs forcefully such that stomach contents may be ejected from the body in a way that propels expelled contents to a distance.

endocrine dysfunction. Other blood testing will include testing to determine levels of growth hormones, thyroid hormone, and follicle-stimulating and luteinizing hormones that may also be abnormal.

Radiology and imaging studies that may be performed include x rays of the head and skull, computed tomography (CT) scans of the head, brain **magnetic resonance imaging** (MRI) and MRI/magnetic imaging **angiography**, which is useful in preoperative planning. Tests to evaluate intellectual and psychological capabilities may also be conducted.

Treatment

Historically, the most common approach to treating craniopharyngioma was radical surgery which was used to remove as much of the tumor as possible in an effort to prevent recurrence. However, complications from radical surgical approaches often resulted in significant morbidity because of the location of the tumor and did not always prevent tumor recurrence with relapse of tumor occurring in as many as 60% of patients. In addition, the mortality rate from radical surgery although declining in recent years, can be as high as 10–25%.

Recent approaches to treating craniopharyngiomas include more conservative surgery followed by external beam **radiation therapy**. Outcomes from this treatment strategy include low rates of recurrence (5–20%) at 5–20 years with low long-term complications. However, radiation therapy may be not a viable treatment option for children less than 3 years of age because of the serious long-term side-effects associated with radiation therapy in this age group.

Patients with tumors that cannot be surgically removed, patients who are not candidates for treatment with radiation therapy, and those that relapse after treatment with surgery and radiation therapy may be candidates for **chemotherapy**. Systemic chemotherapy has not been effective in treating craniopharyngiomas however, some patients may respond to administration of intracavitary/intracystic administration of the chemotherapy agent bleomycin which is administered directly into the tumor cavity via a catheter.

Prognosis

Ten-year overall rates for patients whose tumors were able to be surgically resected range from 86–100%. Ten-year overall survival rates for patients whose tumors were not able to be completely surgically removed and for those whose tumors relapsed after treatment with surgery and radiation therapy range from 57–86%.

Patients require close monitoring of endocrine, ophthalmologic and neuropsychiatric function even after **tumor removal** and subsequent treatment. Assessment of growth and development, hormonal function, ophthalmologic function, and neuropsychiatric function is recommended. For example, problems with the visual field may indicate relapse of tumor. In addition, long-term hormone supplementation is required for virtually all patients diagnosed with craniopharyngioma.

Prevention

As the cause of craniopharyngiomas is not known, there is currently no known way to prevent occurrence of these rare tumors.

Following treatment, patients diagnosed with craniopharyngioma continue to require close follow–up to detect potential recurrence. Current recommendations related to follow-up include screening with brain MRI every 3 months for 1 year, followed by MRI every 6 months for 1 year and then MRI once per year until the fifth year. For patients who received radiation therapy, the recommended follow-up is an MRI every year or every other year for life to screen for the occurrence of a second malignancy.

Craniosacral therapy

Definition

Craniosacral therapy is a holistic healing practice that uses very light touching to balance the craniosacral system in the body, which includes the bones, nerves, fluids, and connective tissues of the cranium and spinal area.

Purpose

According to Dr. John Upledger, craniosacral therapy is ideally suited for attention-deficit hyperactivity disorder, headaches, chronic middle ear infection, **pain**, and general health maintenance. It is recommended for **autism**, **fibromyalgia**, **heart disease**, **osteoarthritis**, **pneumonia**, **rheumatoid arthritis**, chronic sinus infections, and **gastroenteritis** (inflammation of the lining of the stomach or small intestine). It is also used with other therapies to treat **chronic fatigue syndrome**, back pain, and menstrual irregularity. In addition, other craniosacral practitioners have reported benefits for eye dysfunction, **dyslexia**, depression, motor coordination difficulties, temporomandibular joint dysfunction (TMD), hyperactivity, **colic**, **asthma** in babies, floppy baby syndrome, **whiplash**, **cerebral palsy**, certain **birth defects**, and other central nervous system disorders.

Description

Origins

The first written reference to the movement of the spinal nerves and its importance in life, clarity, and "bringing quiet to the heart" is found in a 4,000-year-old text from China. Craniosacral work was referred to as "the art of listening." Bone setters in the Middle Ages also sensed the subtle movements of the body. They used these movements to help reset **fractures** and **dislocations** and to treat headaches.

In the early 1900s, the research of Dr. William Sutherland, an American osteopathic physician, detailed the movement of the cranium and pelvis. Before his research it was believed that the cranium was a solid immovable mass. Sutherland reported that the skull is actually made up of 22 separate and movable bones that are connected by layers of tissue. He called his work cranial **osteopathy**. Nephi Cotton, an American chiropractor and contemporary of Sutherland, called this approach craniology. The graduates of these two disciplines have refined and enhanced these original approaches and renamed their work as

WWW.BOOKBAZ.IR

WILLIAM SUTHERLAND (1873–1954)

William Garner Sutherland studied osteopathy under its founder, Andrew Taylor Still. Dr. Sutherland made his own important discovery while examining the sutures of cranial bones the skull bones that protect the brain. What he noticed is that the sutures were designed for motion. Sutherland termed this motion the *Breath of Life.* Through his experiments and research he determined that primary respiration was essential to all other physiological functions.

When Sutherland developed his techniques for craniosacral therapy, he wanted it to serve as a vehicle for listening to the body's rhythmic motions, and treat the patterns of inertia, when those motions become congested. He believed that the stresses—any physical or emotional trauma—created an imbalance in the body that needed correction to restore it to full health. The therapy is a hands-on method so that the therapist can feel the subtleties of the patterns of movement and inertia. Sutherland felt that this was the way to encourage self-healing and restoration of the body's own mechanisms, taking a holistic approach to creating optimal health.

The Craniosacral Therapy Educational Trust, based on Sutherland's pioneering work, is located at 10 Normington Close, Leigham Court Road, London SW16 2QS, United Kingdom. http://www.cranio.co.uk/

sacro-occipital technique, cranial **movement therapy**, or craniosacral therapy.

Dr. John Upledger, an osteopathic physician, and others at the Department of Biomechanics at Michigan State University, College of Osteopathic Medicine learned of Sutherland's research and developed it further. He researched the clinical observations of various osteopathic physicians. This research provided the basis for Upledger's work that he named craniosacral therapy.

Craniosacral therapy addresses the craniosacral system. This system includes the cranium, spine, and sacrum that are connected by a continuous membrane of connective tissue deep inside the body, called the dura mater. The dura mater also encloses the brain and the central nervous system. Sutherland noticed that cerebral spinal fluid rises and falls within the compartment of the dura mata. He called this movement the primary respiratory impulse; today it is known as the craniosacral rhythm (CSR) or the cranial wave.

Craniosacral therapists can most easily feel the CSR in the body by lightly touching the base of the skull or the sacrum. During a session, they feel for disturbances in the rate, amplitude, symmetry, and quality of flow of the CSR. A therapist uses very gentle touch to balance the flow of the CSR. Once the cerebrospinal fluid moves freely, the body's natural healing responses can function.

A craniosacral session generally lasts 30–90 minutes. The client remains fully clothed and lays down on a massage table while the therapist gently assesses the flow of the CSR. Upledger describes several techniques that may be used in a craniosacral therapy session. The first is energy cyst release. According to Upledger, "This technique is a hands-on method of releasing foreign or disruptive energies from the patient's body. Energy cysts may cause the disruption of the tissues and organs where they are located." The therapist feels these cysts in the client's body and gently releases the blockage of energy.

Sutherland first wrote about a second practice called direction of energy. In this technique the therapist intends energy to pass from one of his hands, through the patient, into the other hand.

The third technique is called myofascial release. This is a manipulative form of bodywork that releases tension in the fascia or connective tissue of the body. This form of bodywork uses stronger touch.

Upledger's fourth technique is position of release. This involves following the client's body into the positions in which an injury occurred and holding it there. When the rhythm of the CSR suddenly stops the therapist knows that the **trauma** has been released.

The last technique is somatoemotional release. This technique was developed by Upledger and is an offshoot of craniosacral therapy. It is used to release the mind and body of the residual effects of trauma and injury that are "locked in the tissues."

The cost of a session varies due to the length of time needed and the qualifications of the therapist. The cost may be covered by insurance when the therapy is performed or prescribed by a licensed health care provider.

Precautions

This gentle approach is extremely safe in most cases. However, craniosacral therapy is not recommended in cases of acute systemic infections, recent skull fracture, intracranial hemorrhage or aneurysm, or herniation of the medulla oblongata (brain stem).

Craniosacral therapy does not preclude the use of other medical approaches.

Side effects

Some people may experience mild discomfort after a treatment. This may be due to re-experiencing a trauma or injury or a previously numb area may come back to life and be more sensitive. These side effects are temporary.

Research and general acceptance

More than 40 scientific papers have been published that document the various effects of craniosacral therapy. There are also 10 authoritative textbooks on this therapy. The most notable scientific papers include Viola M. Fryman's work documenting the successful treatment of 1,250 newborn children with birth defects. Edna Lay and Stephen Blood showed the effects on TMD, and John Wood documented results with psychiatric disorders. The American Dental Association has found craniosacral therapy to be an effective adjunct to orthodontic work. However, the conventional medical community has not endorsed these techniques.

Craniotomy

Definition

Surgical removal of part of the skull to expose the brain.

Purpose

A craniotomy is the most commonly performed surgery for brain **tumor removal**. It may also be done to remove a blood clot and control hemorrhage, inspect the brain, perform a biopsy, or relieve pressure inside the skull.

Precautions

Before the operation, the patient will have undergone diagnostic procedures such as **computed tomography scans** (CT) or **magnetic resonance imaging** (MRI) scans to determine the underlying problem that required the craniotomy and to get a better look at the brain's structure. Cerebral **angiography** may be used to study the blood supply to the tumor, aneurysm, or other brain lesion.

Description

There are two basic ways to open the skull:

- a curving incision from behind the hairline, in front of the ear, arching above the eye
- at the nape of the neck around the occipital lobe

The surgeon marks with a felt tip pen a large square flap on the scalp that covers the surgical area. Following this mark, the surgeon makes an incision into the skin as far as the thin membrane covering the skull bone. Because the scalp is well supplied with blood, the surgeon will have to seal many small arteries. The surgeon then folds back a skin flap to expose the bone.

Using a high speed hand drill or an automatic craniotome, the surgeon makes a circle of holes in the skull, and pushes a soft metal guide under the bone from one hole to the next. A fine wire saw is then moved along the guide channel under the bone between adjacent holes. The surgeon saws through the bone until the bone flap can be removed to expose the brain.

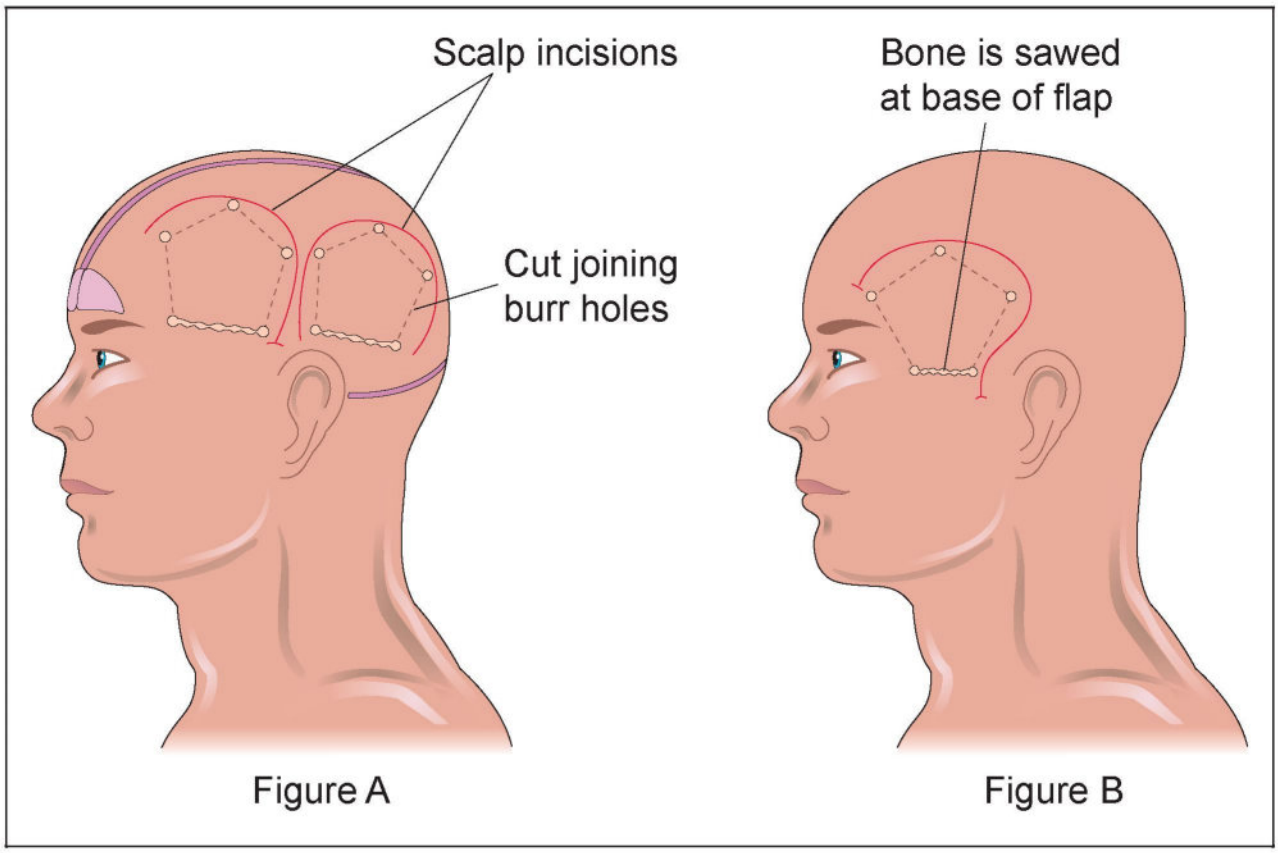
After the surgery for the underlying cause is completed, the piece of skull is replaced and secured with pieces of fine, soft wire. Finally, the surgeon sutures the membrane, muscle, and skin of the scalp.

Preparation

Before the surgery, patients are usually given drugs to ease **anxiety**, and other medications to reduce the risk of swelling, seizures, and infection after the operation. Fluids may be restricted, and a diuretic may be given before and during surgery if the patient has a tendency to retain water. A catheter is inserted before the patient goes to the operating room.

The scalp is shaved in the operating room right before surgery; this is done so that any small nicks in

WWW.BOOKBAZ.IR



A craniotomy is the most commonly performed surgery for brain tumor removal. There are two basic ways to open the skull: a curving incision from behind the hairline in front of the ear and at the nape of the neck (figure A). To reach the brain, the surgeon uses a hand drill to make holes in the skull, pushing a soft metal guide under the bone. The bone is sawed through until the bone flap can be removed to expose the brain (figure B). *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

the skin will not have a chance to become infected before the operation.

Aftercare

Oxygen, painkillers, and drugs to control swelling and seizures are given after the operation. Codeine may be given to relieve the **headache** that may occur as a result of stretching or irritation of the nerves of the scalp that happens during the craniotomy. Some type of drainage from the head may be in place, depending on the reason for the surgery.

Patients are usually out of bed within a day and out of the hospital within a week. Headache and **pain** from the scalp wound can be controlled with medications.

The bandage on the skull should be changed regularly. Sutures closing the scalp will be removed, but soft wires used to reattach the skull are permanent and require no further attention. The patient should avoid getting the scalp wet until all the sutures have been removed. A clean cap or scarf can be worn until the hair grows back.

Risks

Accessing the area of the brain that needs repair may damage other brain tissue. Therefore, the procedure carries with it some risk of brain damage that could leave the patient with some loss of brain function. The surgeon performing the operation can give the patient an assessment of the risk of his or her particular procedure.

Results

While every patient's experience is different depending on the reason for the surgery, age, and overall health, if the surgery has been successful, recovery is usually rapid because of the good supply of blood to the area.

Possible complications after craniotomy include:

- swelling of the brain
- excessive intracranial pressure

KEY TERMS

Craniotome—A type of surgical drill used to operate on the skull. It has a self-controlled system that stops the drill when the bone is penetrated.

- infection
- seizures

C-reactive protein

Definition

C-reactive protein (CRP) is a protein produced by the liver and not normally found in the blood, except for people who smoke, are obese, or have an inflammatory condition somewhere in the body. CRP is measured in samples of blood and reported as ultra-sensitive CRP, US-CRP, or high sensitive CRP, HS-CRP.

Purpose

C-reactive protein appears in response to inflammation, infection, and illnesses such as **heart disease**, cancer, high blood pressure, and connective tissue diseases like **rheumatoid arthritis** and lupus erythematosis.

Individuals vary in the amount of CRP their livers produce. Some people with serious diseases, like rheumatoid arthritis and lupus, may not have elevated blood levels of CRP.

CRP is a sensitive but nonspecific test that signifies inflammation somewhere in the body; it does not help determine where or how serious it is. CRP levels begin rising within a few hours following an injury, surgery, or **heart attack**. Very high CRP levels are found after surgery, acute heart attack, or serious injury. There is a current theory that there is an inflammatory component factor in developing atherosclerotic plaques in the coronary and other major arteries, leading to hardening of the arteries. But, for people at low risk of heart disease, without cardiac symptoms, CRP levels are not useful as screening tests for heart-disease risk.

KEY TERMS

Atherosclerosis—Disease of arteries where cholesterol deposits (plaques) form on the inner surfaces of the arteries, possibly obstructing blood flow.

By taking multiple tests over time, the level of activity of some chronic conditions, like arthritis and other connective tissue diseases, can be followed.

CRP levels are useful in predicting the risk of complications in people with heart or **vascular disease** who have had a **stroke**, heart attack, or coronary treatment procedure like **angioplasty**. But therapy decisions are made on the basis of all clinical findings, not only on CRP levels.

Results

Normal CRP test results are 0–1 mg/L of blood.

Creatine kinase test

Definition

The creatine kinase test measures the blood levels of certain muscle and brain enzyme proteins.

Purpose

Creatine kinase (CK or CPK) is an enzyme (a type of protein) found in muscle and brain. Normally, very little CK is found circulating in the blood. Elevated levels indicate damage to either muscle or brain; possibly from a myocardial infarction (**heart attack**), muscle disease, or **stroke**.

There are three types, or isoforms, of CK:

- CK-I, or BB, is produced primarily by brain and smooth muscle.
- CK-II, or MB, is produced primarily by heart muscle.

WWW.BOOKBAZ.IR

• CK-III, or MM, is produced primarily by skeletal muscle.

Precautions

No special precautions are necessary, except in patients with a bleeding disorder.

Description

A small amount of blood is drawn and used for laboratory analysis.

Preparation

Physical activity may cause a rise in CK levels, especially the CK-III fraction. Therefore, patients should not engage in strenuous physical activity the day of the test. The patient should report any recent injections, falls, or **bruises** that have occurred, as these may elevate CK levels as well.

Aftercare

No aftercare is required, except to keep the puncture site clean while it heals.

Risks

There are no risks to this test beyond the very slight risk of infection at the puncture site.

Results

In females, total CK should be 10–79 units per liter (U/L). In males, total CK should be 17–148 U/L. CK levels are reduced in the first half of **pregnancy**, and increased in the second half. CK levels are elevated in newborns.

The distribution of isoenzymes should be:

• CK-I: 0%
• CK-II: 0–5%
• CK-III: 95–100%.

Abnormal results

Elevation of CK-I may be seen in stroke, extreme **shock**, or **brain tumor**.

Elevation of CK-II is seen after a myocardial infarction. It begins to rise three to six hours after the heart attack, and may peak within 24 hours. It should then return to normal. For this reason, it is a useful marker for recent myocardial infarction, but not for one which occurred more than a day before the test.

KEY TERMS

Skeletal muscles—Muscles that move the skeleton. All of the muscles under voluntary control are skeletal muscles.

Smooth muscles—Muscles that surround the linings of the digestive system, airways, and circulatory system.

Elevation of CK-III indicates skeletal muscle damage. This may occur from normal **exercise**, **trauma**, or muscle disease. CK levels may be very high early on in **muscular dystrophy**, but may fall to normal later as muscle tissue is lost. Elevated CK is also seen in **myositis**, myoglobinuria, **toxoplasmosis**, and **trichinosis**. **Hypothyroidism** may also cause elevated CK.

Creatine phosphokinase test *see* **Creatine kinase test**

Creatinine test

Definition

Creatine is an important compound produced by the body. It combines with phosphorus to make a high–energy phosphate compound in the body. Creatine phosphate is used in skeletal muscle contraction.

Purpose

The creatinine test is used to diagnose impaired kidney function and to determine renal (kidney) damage.

Precautions

A diet high in meat content can cause transient elevations of serum creatinine. Some drugs that may increase creatinine values include gentamicin, cimetidine, heavy-metal chemotherapeutic agents (e.g., cisplatin), and other drugs toxic to the kidneys, such as the **cephalosporins**.

KEY TERMS

Glomerulonephritis—Glomerulonephritis is an inflammation of the filtering units of the kidney (glomeruli). The condition hinders removal of waste products, salt, and water from the bloodstream, leading to serious complications. It is the most common cause of renal failure.

Pyelonephritis—Pyelonephritis is an inflammation of the kidney itself, usually caused by a bacterial infection. In its most serious form, complications can include high blood pressure (hypertension) and renal failure.

Description

The creatinine test is used to measure the amount of creatinine in the blood. Because creatinine is a nonprotein end-product of creatine phosphate, which is used in skeletal muscle contraction, the daily production of creatine, and the following product, creatinine, depends on muscle mass, which fluctuates very little.

Creatinine is excreted entirely by the kidneys, and therefore is directly related to renal function. When the kidneys are functioning normally, the serum creatinine level should remain constant and normal. Slight increases in creatine levels can appear after meals, especially after ingestion of large quantities of meat, and some diurnal variation may occur, with a low point at 7 a.m. and a peak at 7 p.m. Serious renal disorders, such as **glomerulonephritis**, **pyelonephritis**, and urinary obstruction, will cause abnormal elevations.

The creatinine level is interpreted in conjunction with another kidney function test called the Blood Urea Nitrogen (BUN). The serum creatinine level has much the same significance as the BUN but tends to rise later. Because of this, determinations of creatinine help to chronicle a disease process. Generally, a doubling of creatinine suggests a 50% reduction in kidney filtration rate.

Preparation

The creatinine test requires a blood sample. It is recommended that the patient be **fasting** (nothing to eat or drink) for at least eight hours before the test. The physician may also require that ascorbic acid (vitamin C), **barbiturates**, and **diuretics** be withheld for 24 hours.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Normal values can vary from laboratory to laboratory, but are generally in the following ranges:

- adult female: 0.5–1.1 mg/dL
- adult male: 0.6–1.2 mg/dL
- adolescent: 0.5–1.0 mg/dL
- child: 0.3–0.7 mg/dL
- infant: 0.2–0.4 mg/dL
- newborn: 0.3–1.2 mg/dL

Variations between sources for serum creatinine normal ranges are greater than for other important tests. For example, due to the greater amount of muscle mass generally present, males normally demonstrate higher creatinine levels than females. Also, because the kidney filtration rate normally increases in **pregnancy**, serum creatinine should be slightly less during such periods. In older patients, creatinine is reduced because of decreased muscle mass. Similarly, other patients may have creatinine levels in which muscle abnormalities must be taken into consideration, such as long-term corticosteroid therapy, high thyroid (**hyperthyroidism**), **muscular dystrophy**, or **paralysis**.

Abnormal results

Two to 4 mg/dL indicate the presence of impairment of renal function. Greater than 4 mg/dL indicates serious impairment in renal function.

Creutzfeldt-Jakob disease

Definition

Creutzfeldt-Jakob disease (CJD) is a transmissible, rapidly progressing, neurodegenerative disorder called a spongiform degeneration related to "mad cow disease."

Description

Before 1995, Creutzfeldt-Jakob disease was not well known outside the medical profession. Even within it, many practitioners did not know much about it. Most doctors had never seen a case. With the recognition of a so-called "new variant" form of CJD and the strong possibility that those with it became infected simply by eating contaminated beef, CJD has become one of the most talked-about diseases in the world. Additionally, the radical theory that the infectious agent is a normal protein that has been changed in its form also has sparked much interest.

First described in the early twentieth century independently by Creutzfeldt and Jakob, CJD is a neurodegenerative disease causing a rapidly progressing dementia ending in death, usually within eight months of symptom onset. It also is a very rare disease, affecting only about one in every million people throughout the world. In the United States, CJD is thought to affect about 250 people each year. CJD affects adults primarily between ages 50 and 75.

Spongiform encephalopathies

The most obvious pathologic feature of CJD is the formation of numerous fluid-filled spaces in the brain (vacuoles) resulting in a sponge-like appearance. CJD is one of several human "spongiform encephalopathies," diseases that produce this characteristic change in brain tissue. Others are kuru; Gerstmann-Straussler-Scheinker disease, a genetic disorder predominantly characterized by cerebellar ataxia (a kind of movement disorder); and fatal familial insomnia, with symptoms of progressive sleeplessness, weakness, and dysfunction of the nervous system that affects voluntary and involuntary movements and functions.

Kuru was prevalent among the Fore people in Papua, New Guinea, and spread from infected individuals after their deaths through the practice of ritual cannibalism, in which the relatives of the dead person honored him by consuming his organs, including the brain. Discovery of the infectious nature of kuru won the Nobel Prize for Carleton Gadjusek in 1976. The incubation period for kuru was 4–30 years or more. While kuru has virtually disappeared since these cannibalistic practices stopped, several new cases continue to arise each year.

Cases of CJD have been grouped into three types: familial, iatrogenic, and sporadic.

- Familial CJD, representing 5–15% of cases, is inherited in an autosomal dominant manner, meaning that either parent may pass along the disease to a child, who then may develop CJD later in life.
- Iatrogenic CJD occurs when a person is infected during a medical procedure, such as organ donation, blood transfusion, or brain surgery. The rise in organ donation has increased this route of transmission; grafts of infected corneas and dura mater (the tissue covering the brain) have been shown to transmit CJD. Another source is hormones concentrated from the pituitary glands of cadavers, some of whom carried CJD, for use in people with growth hormone deficiencies. Iatrogenic infection from exposure to nerve-containing tissue represents a small fraction of all cases. The incubation period after exposure to the infectious agent is very long and is estimated to be from less than 10 to more than 30 years. It remains unlikely, but not impossible, that blood from patients with CJD is infectious to others by transfusion.
- Sporadic CJD represents at least 85% of all cases. Sporadic cases have no identifiable source of infection. Death usually follows first symptoms within eight months.

Animal forms and "mad cow disease"

Six forms of spongiform encephalopathies are known to occur in other mammals: scrapie in sheep, recognized for more than 200 years; chronic wasting disease in elk and mule deer in Wyoming and Colorado; transmissible mink encephalopathy; exotic ungulate encephalopathy in some types of zoo animals; feline spongiform encephalopathy in domestic cats; and bovine spongiform encephalopathy (BSE) in cows.

BSE was first recognized in Britain in 1986. Besides the spongiform changes in the brain, BSE causes dementia-like behavioral changes—hence the name "mad cow disease." BSE was thought to be an altered form of scrapie, transmitted to cows when they were fed sheep offal (slaughterhouse waste) as part of their feed, but researchers believe it is a primary cattle disease spread by contaminated feed.

The use of slaughterhouse offal in animal feed has been common in many countries and has been practiced for at least 50 years. The trigger for the BSE epidemic in Great Britain seems to have come in the

early 1980s, when the use of organic solvents for preparation of offal was altered there. It is possible that these solvents had been destroying the agent called a prion, thereby preventing infection, and that the change in preparation procedure opened the way for the agent to "jump species" and cause BSE in cows that consumed scrapie-infected meal. The slaughter of infected (but not yet visibly sick) cows at the end of their useful farm lives, and the use of their carcasses for feed, spread the infection rapidly and widely. For at least a year after BSE was first recognized in British herds, infected bovine remains continued to be incorporated into feed, spreading the disease still further. Although milk from infected cows never has been shown to pass the infectious agent, passage from infected mother to calf may have occurred through unknown means. Researchers also have tried to confirm how to stop infection of the human food chain once the disease spread among cows. In 2003, a study reported that it spread through nervous system tissue in processed meat and that proper temperature and pressure controls could help ensure safety of commercial beef.

Beginning in 1988, the British government took steps to stop the spread of BSE, banning the use of bovine offal in feed and other products and ordering the slaughter of infected cows. By then, the slow-acting agent had become epidemic in British herds. In 1992, it was diagnosed in more than 25,000 animals (1% of the British herd). By mid-1997, the cumulative number of BSE cases in the United Kingdom had risen to more than 170,000. The feeding ban stemmed the tide of the epidemic; however, the number of new cases each week fell from a peak of 1,000 in 1993 to less than 300 two years later.

The export of British feed and beef to member countries was banned by the European Union, but cases of BSE had developed in Europe by then as well; however, by mid-1997, only about 1,000 cases had been identified. In 1989, the United States banned import of British beef and began monitoring United States herds in 1990. In December 2003, the first case of BSE was discovered in the United States. This prompted recommendations of new safeguards to prevent further spread. Among these were regulations banning animal blood in cattle feed.

Variant CJD: The human equivalent of mad cow disease

From the beginning of the BSE epidemic, scientists and others in Britain feared that BSE might jump species again to infect humans who had consumed infected beef. This, however, had never occurred in scrapie from sheep, a disease known for hundreds of years. In 1996, the first report of this possibility occurred and the fear seemed to be realized with the first cases of a new variant of Creutzfeldt-Jacob disease, termed nvCJD, now just vCJD. Its victims are much younger than the 60–65 year old average for CJD, and the time from symptom onset to death has averaged 12 months or more instead of eight. The disease appears to cause more psychiatric symptoms early on. EEG abnormalities characteristic of CJD are not typically seen in vCJD.

By early 2004, CJD had claimed 143 victims in Great Britain and 10 in other countries. It is of major concern that the number of cases per year seems to be increasing by a factor of 1.35 each year. The only known case in the United States to date had been acquired while the person had been in Great Britain.

Evidence is growing stronger that vCJD is in fact caused by BSE:

- almost all of the cases so far have occurred in Great Britain, the location of the BSE epidemic
- BSE injected into monkeys produces a disease very similar to vCJD
- BSE and vCJD produce the same brain lesions after the same incubation period when injected into laboratory mice
- brain proteins isolated from vCJD victims, but not from the other forms of CJD, share similar molecular characteristics with brain proteins of animals that died from BSE

Researchers now treat the BSE-vCJD connection as solidly established.

Assuming that BSE is the source, the question that has loomed from the beginning has been how many people will eventually be affected. Epidemiological models once placed estimates at tens of thousands, but in 2003, scientists predicted a quicker end to the epidemic and have substantially lowered the numbers expected to contract the disease. The exact incubation period of vCJD in humans is about 10 to 20 years or longer, so it is more difficult to predict the number of cases. Researchers know that some people are more susceptible to vCJD, including young people age 10 to 20 years old.

Causes and symptoms

Causes

It is clear that Creutzfeldt-Jakob disease is caused by an infectious agent, but it is not yet clear what type of agent that is. Originally assumed to be a virus, evidence is accumulating that, instead, CJD is caused

WWW.BOOKBAZ.IR

by a protein called a prion (PREE-on, for "proteinaceous infectious particle") transmitted from victim to victim. The other spongiform encephalopathies also are hypothesized to be due to prion infection.

If this hypothesis is proven true, it would represent one of the most radical new ideas in biology since the discovery of deoxyribonucleic acid (DNA). All infectious diseases, in fact all life, use nucleic acids—DNA or ribonucleic acid (RNA)—to code the instructions needed for reproduction. Inactivation of the nucleic acids destroys the capacity to reproduce. However, when these same measures are applied to infected tissue from spongiform encephalopathy victims, infectivity is not destroyed. Furthermore, purification of infected tissue to concentrate the infectious fraction yields protein, not nucleic acid. While it remains possible that some highly stable nucleic acid remains hidden within the purified protein, this is seemingly less and less likely as further experiments are done. The "prion hypothesis," as it is called, is now widely accepted, at least provisionally, by most researchers in the field. The most vocal proponent of the hypothesis, Stanley Prusiner, was awarded the Nobel Prize in 1997 for his work in the prion diseases.

A prion is an altered form of a normal brain protein. The normal protein has a helical shape along part of its length. In the prion form, a sheet structure replaces the helix. According to the hypothesis, when the normal form interacts with the prion form, some of its helical part is converted to a sheet, thus creating a new prion capable of transforming other normal forms. In this way, the disease process resembles crystallization more than typical viral infection, in which the virus commands the host's cellular machinery to reproduce more of the virus. Build-up of the sheet form causes accumulation of abnormal protein clumps and degeneration of brain cells, which is thought to cause the disease.

The brain protein affected by the prion, called PrP, is part of the membrane of brain cells, but its exact function is unknown. Exposure to the infectious agent is, of course, still required for disease development. Prion diseases are not contagious in the usual sense, and transmission from an infected person to another person requires direct inoculation of infectious material.

Familial CJD, on the other hand, does not require exposure, but develops through the inheritance of other, more disruptive mutations in the gene for the normal PrP protein. The other two inherited human prion diseases, Gerstmann-Straussler-Scheinker disease and fatal familial insomnia, involve different mutations in the same gene.

The large majority of CJD cases are sporadic, meaning they have no known route of infection or genetic link. Causes of sporadic CJD are likely to be diverse and may include spontaneous genetic mutation, spontaneous protein changes, or unrecognized exposure to infectious agents. It is highly likely that future research will identify more risk factors associated with sporadic CJD.

Symptoms

About one in four people with CJD begin their illness with weakness, changes in sleep patterns, weight loss, or loss of appetite or sexual drive. A person with CJD may first complain of visual disturbances, including double vision, blurry vision, or partial loss of vision. Some visual symptoms are secondary to cortical blindness related to death of nerve cells in the occipital lobe of the brain responsible for vision. This form of visual loss is unusual in that patients may be unaware that they are unable to see. These symptoms may appear weeks to months before the onset of dementia.

The most characteristic symptom of CJD is rapidly progressing dementia, or loss of mental function. Dementia is marked by:

- memory loss
- impaired abstraction and planning
- language and comprehension disturbances
- poor judgment
- disorientation
- decreased attention and increased restlessness
- personality changes and psychosis
- hallucinations

Muscle spasms and jerking movements, called myoclonus, are also a prominent symptom of CJD. Balance and coordination disturbance (ataxia), is common in CJD, and is more pronounced in nvCJD. Stiffness, difficulty moving, and other features representing Parkinson's disease are seen and can progress to akinetic mutism, which is a state of being unable to speak or move.

Diagnosis

CJD is diagnosed by a clinical neurological exam and electroencephalography (EEG), which shows characteristic spikes called triphasic sharp waves. Magnetic resonance imaging (MRI) or computed tomography scans (CT) should be done to exclude

KEY TERMS

Autosomal dominant inheritance—A pattern of inheritance in which a trait will be expressed if the gene is inherited from either parent.

Encephalopathy—Brain disorder characterized by memory impairment and other symptoms.

Iatrogenic—Caused by a medical procedure.

Nucleic acids—The cellular molecules DNA and RNA that act as coded instructions for the production of proteins and are copied for transmission of inherited traits.

other forms of dementia, and in CJD typically shows atrophy or loss of brain tissue. Lumbar puncture, or spinal tap, may be done to rule out other causes of dementia (as cell count, chemical analysis, and other routine tests are normal in CJD) and to identify elevated levels of marker proteins known as 14-3-3. Another marker, neuron-specific enolase, may also be increased in CJD. CJD is conclusively diagnosed after death by brain autopsy. Scientists are investigating whether testing lymphatic tissue such as the tonsil may be an early tool in vCJD diagnosis. Additionally, recent studies have suggested that other blood tests may be useful as well.

Treatment

There is no cure for CJD, and no treatment that slows the progression of the disease. Drug therapy and nursing care are aimed at minimizing psychiatric symptoms and increasing patient comfort. However, the rapid progression of CJD frustrates most attempts at treatment, since decreasing cognitive function and more prominent behavioral symptoms develop so quickly. Despite the generally grim prognosis, a few CJD patients progress more slowly and live longer than the average; for these patients, treatment will be more satisfactory. Scientists are investigating whether some medicines that can "break" the abnormal protein form may be useful and whether a vaccine could help.

Prognosis

Creutzfeldt-Jakob disease has proven invariably fatal, with death following symptom onset by an average of eight months. About 5% of patients live longer than two years. Death from vCJD has averaged approximately 12 months after onset. However, in 2003, clinicians reported improvement in a patient with vCJD who received a new experimental drug called Pentosan.

Prevention

There is no known way to prevent sporadic CJD, by far the most common type. Not everyone who inherits the gene mutation for familial CJD will develop the disease, but at present, there is no known way to predict who will and who will not succumb. The incidence of iatrogenic CJD has fallen with recognition of its sources, the development of better screening techniques for infected tissue, and the use of sterilization techniques for surgical instruments that inactivate prion proteins. Fortunately, scientists are making progress. In 2003, researchers announced that they had uncovered the basis for diagnosing, treating and possibly preventing prion diseases such as vCJD. Their research possibly could lead to a vaccine and immunotherapy drugs.

Strategies for prevention of vCJD are a controversial matter, as they involve a significant sector of the agricultural industry and a central feature of the diet in many countries. The infectious potential of contaminated meat is unknown, because the ability to detect prions within meat is limited. Surveillance of North American herds strongly suggests there is no BSE here, and strict regulations on imports of European livestock make future outbreaks highly unlikely. Therefore, avoidance of all meat originating in North America, simply on grounds of BSE risk, is a personal choice unsupported by current data.

Cri du chat syndrome

Definition

Cri du chat syndrome occurs when a piece of chromosomal material is missing from a particular region on chromosome 5. The disorder is also called cat cry syndrome or chromosome deletion 5p syndrome. Individuals with this syndrome have unusual facial features, poor muscle tone (hypotonia), small head size (microcephaly), and intellectual disabilities (ID). A classic feature of the syndrome is the cat-like cry made by infants with this disorder.

Description

Dr. Jerome Lejeune first described cri du chat syndrome in 1963. The syndrome is named for the cat-like cry made by infants with this genetic disorder. *Cri du chat* means "cat's cry" in French. This unusual cry is caused by abnormal development of the larynx (organ in the throat responsible for voice production). Cri du chat syndrome is also called 5p deletion syndrome because it is caused by a deletion, or removal, of genetic material from chromosome 5. The deletion that causes cri du chat syndrome occurs on the short or "p" arm of chromosome 5. This deleted genetic material is vital for normal development. Absence of this material results in the features associated with cri du chat syndrome.

A high-pitched mewing cry during infancy is a classic feature of cri du chat. Infants with cri du chat also typically have low birth weight, slow growth, a small head (microcephaly) and poor muscle tone (hypotonia). Infants with cri du chat may have congenital heart defects. Individuals with cri du chat syndrome have language difficulties, delayed motor skill development, and intellectual disabilities. Behavioral problems may also develop as the child matures.

It has been estimated that cri du chat syndrome occurs in one of every 50,000 live births. It accounts for 1 in every 500 cases of ID. According to the 5p minus Society, approximately 50–60 children are born with cri du chat syndrome in the United States each year. It can occur in all races and in both sexes, although there is a slight female predominance. The male:female ratio is 3:4.

Causes and symptoms

Cri du chat is the result of a chromosome abnormality—a deleted piece of chromosomal material on chromosome 5. In about 80% of patients, the defective chromosome comes from the father. In 90% of patients with cri du chat syndrome, the deletion is sporadic. This means that it happens randomly and is not hereditary. If a child has cri du chat due to a sporadic deletion, the chance the parents could have another child with cri du chat is 1%. In approximately 10% of patients with cri du chat, there is a hereditary chromosomal rearrangement that causes the deletion. If a parent has this rearrangement, the risk for them to have a child with cri du chat is greater than 1%.

The severity of ID in cri du chat syndrome is correlated with the extent of deletion of delta-catenin, a protein with an important role in brain functioning. The more extensive the deletion, the more profound the mental dysfunction.

An abnormal larynx causes the unusual cat-like cry made by infants that is a hallmark of the syndrome. As children with cri du chat get older, the cat-like cry becomes less noticeable. This feature can make the diagnosis more difficult in older patients. In addition to the cat-like cry, individuals with cri du chat also have unusual facial features. These facial differences can be very subtle or more obvious. Microcephaly (small head size) is common. During infancy many patients with cri du chat do not gain weight or grow normally. Approximately 30% of infants with cri du chat have a congenital heart defect. Hypotonia (poor muscle tone) is also common, leading to problems with eating and slow, but normal development. ID is present in all patients with cri du chat, but the degree of ID varies among patients.

Diagnosis

During infancy, the diagnosis of cri du chat syndrome is strongly suspected if the characteristic cat-like cry is heard. If a child has this unusual cry or other features seen in cri du chat syndrome, chromosome testing should be performed. Chromosome analysis provides the definitive diagnosis of cri du chat syndrome and can be performed from a blood test. Chromosome analysis, also called karyotyping, involves staining the chromosomes and examining them under a microscope. In some cases the deletion of material from chromosome 5 can be easily seen. In

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Centromere—The centromere is the constricted region of a chromosome. It performs certain functions during cell division.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Congenital—Refers to a disorder that is present at birth.

Deletion—The absence of genetic material that is normally found in a chromosome. Often, the genetic material is missing due to an error in replication of an egg or sperm cell.

Hypotonia—Reduced or diminished muscle tone.

Karyotyping—A laboratory procedure in which chromosomes are separated from cells, stained and arranged so that their structure can be studied under the microscope.

Microcephaly—An abnormally small head.

other cases, further testing must be performed. FISH (fluorescence in-situ hybridization) is a special technique that detects very small deletions. The majority of the deletions that cause cri du chat syndrome can be identified using the FISH technique.

Cri du chat syndrome can be detected before birth if the mother undergoes **amniocentesis** testing or **chorionic villus sampling** (CVS). This testing would only be recommended if the mother or father is known to have a chromosome rearrangement, or if they already have a child with cri du chat syndrome.

Treatment

There is no cure for cri du chat syndrome. Treatment consists of supportive care and developmental therapy. Behavioral modification therapy has been found to be useful to control head-banging, hyperactivity, and other behavioral problems that emerge during later childhood.

Prognosis

Individuals with cri du chat have a 10% mortality during infancy due to complications associated with congenital heart defects, hypotonia, and feeding difficulties. Once these problems are controlled, most individuals with cri du chat syndrome have a normal lifespan. The degree of ID can be severe. However, a recent study suggested that the severity is somewhat affected by the amount of therapy received.

Crib death *see* **Sudden infant death syndrome**

Crohn's disease

Definition

Crohn's disease is a chronic inflammatory disorder that affects the digestive tract. It is characterized by cramping pains, **diarrhea**, and sometimes nausea or **vomiting**.

Description

Crohn's disease is named for Dr. Burrill Bernard Crohn (1884–1983) who, with his colleagues, first described the disease in 1932. Crohn's disease can affect any part of the digestive system, but it develops most often in the section of the small intestine just before the large intestine begins. This region is called the ileum, and Crohn's disease that develops there is sometimes called ileitis. The other common site for Crohn's disease is in the colon or large intestine.

Crohn's disease is one of several inflammatory bowel diseases. It can be mistaken for ulcerative **colitis**, as both these diseases cause watery or bloody diarrhea and abdominal cramps or **pain**. However, ulcerative colitis affects only the layer of cells that line the intestine, forming sores or **ulcers** on this surface. Crohn's disease begins in these same surface cells but can gradually damage all four layers of the intestine and sometimes create a hole (**fistula**) through the intestine and into other tissue. Another major difference between Crohn's disease and ulcerative colitis is that Crohn's disease can develop simultaneously in several spots in the digestive tract, resulting in areas damaged with patches with healthy tissue in between. Ulcerative colitis, by contrast, spreads uniformly across an area. Crohn's disease is somewhat treatable, but not curable, and can cause many complications beyond the digestive system. Eventually, the walls of the intestine thicken, and blockages may occur that can only be corrected by surgery.

A barium x ray showing the colon of a patient with Crohn's disease where the large and small intestines join (bottom left). *(Custom Medical Stock Photo, Inc.)*

In some cases of Crohn's disease, the underlying layers of intestinal tissue are damaged also, leading to complete perforation (puncturing) of the wall of the intestine. This form of the disease is sometimes called penetrating Crohn's disease. Penetrating disease may cause a serious infection in the abdomen or the formation of fistulas. In Crohn's disease, fistulas are most likely to form in the area around the anus, leading to the formation of abscesses (pus-filled sores). About 30% of patients with Crohn's disease develop fistulas.

Another subtype of Crohn's disease is called stricturing disease. *Stricture* is the medical term for an abnormal narrowing of a hollow organ such as the bowel. In stricturing disease, the inflammation and

swelling of tissue inside the bowel leads to changes in the size of the patient's stools and eventual blockage of the intestinal passages. Severe abdominal cramping is often an indication of stricturing disease, as are **nausea and vomiting**.

Risk factors

Risk factors for Crohn's disease include a family history of the disorder, a history of heavy **smoking**, and Eastern European Jewish ethnicity. The disease is slightly more common in women.

Demographics

It is estimated that there are about 500,000 people with Crohn's disease in the United States. Another statistic given by some doctors is 7 cases per 100,000 in the general population in Canada and the United States. Crohn's disease is primarily a disorder found in adults, most often beginning in late adolescence or the early adult years. The most common age at onset is between 15 and 30 years, although the disorder may begin at any age.

The rate of Crohn's disease in North America increased after the 1960s, although the reasons for the increase are not well known. Southern Europe, South America, Africa, and Asia have considerably lower rates of the disease—as low as 0.08–0.5 cases per 100,000 people. Around the world, rates of Crohn's disease are higher in cities than in rural areas and higher among people with higher incomes than among lower-income groups.

One argument for the presence of a genetic factor in Crohn's disease is that it runs in some families; people who have a sibling with the disease are 30 times more likely to develop it than the normal population. Crohn's disease is also relatively common among certain ethnic groups, particularly Jews of Eastern European origin. A two-to-four-fold increase in the frequency of Crohn's disease has been found among the Jewish population in the United States, Europe, and South Africa compared to other ethnic groups.

Causes and symptoms

Causes

At one time, researchers thought that **stress** and diet caused Crohn's disease, particularly high-fat foods. Later researchers learned that these are not factors, although both stress and diet can worsen symptoms in people who already have the disease. What researchers do know is that Crohn's disease is caused by an inappropriate immune system reaction that affects cells in the digestive tract. Beyond that, the reasons why some people develop the disease are not clear, although smoking does increase the risk, and smokers have more severe symptoms.

There is almost certainly an inherited component that predisposes some people to the disease. Individuals who are blood relatives of a parent, sibling, or child with Crohn's disease are 30 times more likely to develop the disease than the general population. Scientists believe multiple genes are involved in development of the disease. However, more than genetics determines who gets Crohn's disease, because among identical twins only in 44% of the cases do both individuals develop the disease. Researchers have found mutated (altered) genes in many, but not all, people who have Crohn's disease but do not have a clear understanding of what these genes do.

One theory is that interactions among genes, the environment, the individual's health, and body chemistry affect a person's risk of developing Crohn's disease. When foreign materials (antigens) enter the body, the immune system produces antibodies, which are proteins that neutralize the foreign invader. One theory about Crohn's disease is that some foreign organism or material stimulates an immune system response in the digestive system, and then through an error in genetic control, the response cannot be turned off. Another theory suggests that the cells of the immune system mistake good bacteria, food, or some other substance that is normally present in the digestive tract as a foreign substance and make antibodies against it. Either way, an inappropriate immune system response occurs that appears to be the root cause of the symptoms people with Crohn's disease experience.

Symptoms

Symptoms of Crohn's disease vary, depending on the location of the damaged cells and the length of time the individual has had the disease. Symptoms can be mild or severe. They can develop suddenly or gradually, and they may improve or even disappear and then worsen many times throughout an individual's life. Some people may have only occasional episodes of diarrhea, for example, whereas others may have 20–30 bowel movements in a single day that interfere with sleep, work, school, or other activities. In general, symptoms can be divided into those that affect the digestive tract and those that affect the rest of the body.

The most common symptoms that affect the digestive tract are:

- chronic diarrhea, the most common symptom

WWW.BOOKBAZ.IR

- abdominal pain or cramps, often in the lower right portion of the abdomen
- rectal bleeding
- blood in the stool or black, tarry stools
- ulcers in the digestive tract, usually in the intestine
- fistulas, or holes, in the intestine that connect the intestine to other parts of the body such as the bladder, stomach, vagina, or another section of bowel
- nausea and vomiting, usually from Crohn's disease in the stomach
- abscesses, fistulas, and ulcers around the anus, usually from Crohn's disease in the colon (occurs in about 45% of patients)
- constipation, usually after many years when the bowel has thickened and the diameter of the intestine has narrowed

Symptoms of Crohn's disease also appear in other systems in the body. Some are the result of infection when fistulas develop. Others come from poor absorption of nutrients in the intestine over a long period. Some symptoms that occur outside the digestive tract are:

- persistent low-grade fever
- loss of appetite and weight loss
- fatigue
- anemia from blood loss and/or poor iron absorption
- skin infections
- eye infections
- arthritis and sore joints, usually in the large joints, such as the knees or hip
- osteoporosis from poor calcium and vitamin D absorption
- poor blood clotting from inadequate vitamin K absorption
- stunted growth in children
- delayed puberty

Diagnosis

Several gastrointestinal diseases can resemble the more common symptoms of Crohn's disease. These include ulcerative colitis, **irritable bowel syndrome**, intestinal parasites, and intestinal obstruction. Thus, in diagnosing Crohn's disease, it is important to distinguish it from other disorders. Normally, the physician begins with recording a medical and family history and standard blood and stool tests. The next step toward diagnosis is usually imaging studies, most often an upper GI series. An upper GI series, sometimes called a barium swallow, includes x rays of the esophagus, stomach, and upper part of the intestine. The patient drinks a solution of a barium compound to improve contrast on the x rays, thus the name barium swallow.

An upper **endoscopy** or a **colonoscopy** is another routine part of the diagnostic procedure. An upper endoscopy is done if abnormalities appear to be in the esophagus, stomach, or upper part of the small intestine (the duodenum). A colonoscopy uses the same technique to examine the colon. These procedures are usually performed in a doctor's office or an outpatient clinic under light **sedation**. A tube called an endoscope is moved down the throat and into the stomach and duodenum or up the rectum and into the colon. At the end of the endoscope is a tiny camera that allows the doctor to see if there is damage to the cells lining the digestive tract. During this procedure, the doctor also removes small tissue samples (biopsies) in order to look for abnormal cells under the microscope.

Special blood tests are available that can help differentiate between Crohn's disease and ulcerative colitis. These tests may be done if the results of other tests are questionable. According to the Crohn's & Colitis Foundation of America, it is quite difficult to tell these two diseases apart in about 10% of patients. Blood tests may also reveal an increase in certain types of white blood cells, an indication that some type of inflammation or infection is occurring in the body or presence of anemia and other signs of **malnutrition** due to malabsorption. Stool samples may be examined to make sure that no infectious agent is causing the diarrhea, and to see whether the waste products contain blood.

Treatment

There is no cure for Crohn's disease. Treatment is aimed at controlling inflammation, preventing vitamin and mineral deficiencies, and relieving symptoms. Treatment options include a combination of drugs, biologic therapies, **nutritional supplements**, and surgery.

Individuals with mild to moderate Crohn's disease are usually treated first with anti-inflammatory drugs, such as sulfasalazine (Azulfidine) or mesalamine (Asacol, Rowasa, Canasa). Individuals with moderate to severe Crohn's disease often are prescribed corticosteroid drugs. Prednisone (Deltasone, Orasone, Meticorten) is often the corticosteroid of choice. These drugs have significant side effects and cannot be used for long-term suppression of symptoms. **Antibiotics** are used to treat infection that may develop, for example, from fistula formation.

Biologic therapies use man-made antibodies. Infliximab (Remicade) is a laboratory-made antibody that blocks the production of an immune system factor that causes inflammation. This treatment appears to have a good success rate for relieving symptoms.

Medical treatment becomes less effective over time. When medical treatment fails, or if the intestine becomes so thickened that blockages occur, surgery may be necessary. About 80% of all people with Crohn's disease eventually need surgery. Surgery to remove part of the intestine usually relieves symptoms for a few years, but surgery is not a cure for Crohn's disease, and symptoms almost always return within a few years. In cases in which the disease is located in the large intestine (colon), the surgeon may have to remove the entire colon in a procedure called a **colostomy**. In this procedure, an opening called a stoma is made in the wall of the abdomen and a portion of the remaining colon is attached to the stoma. The person's body wastes pass through the stoma and are collected in a special bag attached to the outside of the body.

KEY TERMS

Abscess—A pocket of pus formed by an infection.

Antibody—A protein produced by the immune system to fight infection or rid the body of foreign material. The foreign material that stimulates the production of antibodies is called an antigen. Specific antibodies are produced in response to each different antigen and can only inactivate that particular antigen.

Anus—The opening from the rectum to the outside of the body through which stools pass. The opening and closing of the anus is controlled by a strong ring of muscles under somewhat voluntary control.

Mineral—An inorganic substance that is necessary in small quantities for the body to maintain good health. Examples are zinc, copper, and iron.

Vitamin—A nutrient that the body needs in small amounts to remain healthy but that the body cannot manufacture for itself and must acquire through diet.

Nutrition and dietetic concerns

People with Crohn's disease tend to have vitamin and mineral deficiencies because damage to the lining of the intestine interferes with the absorption of nutrients, and chronic diarrhea hastens the loss of other nutrients. These deficiencies can cause specific disorders in other parts of the body. In addition, children with Crohn's disease may need special high-calorie, high-nutrient liquid supplements to maintain normal growth. A nutritionist consulting with the patient's gastroenterologist can help determine the best diet and supplements to prevent nutritional deficiencies and may suggest increased fluid intake.

Although eating certain foods does not cause Crohn's disease, specific foods can worsen symptoms. Many people with Crohn's disease become lactose intolerant and must limit or eliminate dairy products from their diet. Alcohol, high fiber foods (such as popcorn), and spicy foods can worsen diarrhea and abdominal cramping. Individuals can use food diaries to identify specific foods that may trigger their symptoms.

Therapy

Crohn's disease can be very disruptive. Individuals may be reluctant to go places or engage in certain activities because frequent diarrhea requires them to be near a toilet. Support groups, either on the Internet or in person, help many people adjust to the difficulties of living with this chronic disease. Other people find that **psychotherapy** (talk therapy), guided by a psychologist or psychiatrist experienced in the stresses of chronic illness, can help them make a better adjustment to life with Crohn's disease.

Prognosis

Crohn's disease is a lifelong disease. Symptoms may improve or disappear for periods, but overall, symptoms and complications tend to worsen. Most people with Crohn's disease eventually need surgery as the disease becomes less and less responsive to medication. Living with Crohn's disease can be a difficult challenge that requires major lifestyle adjustments. The chance of a shortened life span or serious complications increases with the duration of the illness; patients with Crohn's disease also have an increased risk of colorectal cancer. The disease itself, however, is rarely fatal.

Prevention

Crohn's disease cannot be prevented. However, some research indicates that a possible benefit of

WWW.BOOKBAZ.IR

being physically active is in its preventing Crohn's. Apparently the risk of the disease is lower among active rather than sedentary individuals.

Croup

Definition

Croup is a common childhood ailment. Typically, it arises from a viral infection of the larynx (voice box) and is associated with mild upper respiratory symptoms such as a runny nose and **cough**. The key symptom is a harsh barking cough. Croup usually is not serious, and most children recover within a few days. In a small percentage of cases, a child develops breathing difficulties and may need medical attention.

Demographics

Croup is most common in children between ages one and two years, with an incidence of 5–6 cases per 100 population. It accounts for about 15% of children's doctor and emergency room visits in the United States. The number of cases peaks in late fall and early winter.

Description

At one time, the term croup was primarily associated with **diphtheria**, a life-threatening respiratory infection. Owing to widespread immunization, diphtheria has become rare in the United States and other parts of the developed world, and croup currently refers to a mild viral infection of the larynx. Croup is also known as laryngotracheitis, a medical term that describes the inflammation of the trachea (windpipe) and larynx.

Parainfluenza viruses are the typical root cause of the infection, but **influenza** (flu) and cold viruses may sometimes be responsible. All of these viruses are highly contagious and easily transmitted between individuals via sneezing and coughing. Children between the ages of three months and six years are usually affected, with the greatest incidence at one to two years of age. The characteristic harsh barking of a croupy cough can be very distressing, but it rarely indicates a serious problem. Most children with croup can be treated very effectively at home; however, 1–5% may require medical treatment.

Croup may sometimes be confused with more serious conditions, such as **epiglottitis** or bacterial tracheitis. These ailments arise from bacterial infection and must receive medical treatment.

Causes and symptoms

The larynx and trachea may become inflamed or swollen from an upper respiratory viral infection. The hallmark sign of croup is a harsh, barking cough. This

KEY TERMS

Corticosteroid drug—A medication that acts like a type of hormone (cortisol) produced by the adrenal gland of the body. Corticosteroids produced by the body stimulate specific types of functional activity. As a drug, a corticosteroid (sometimes just called steroid) helps treat inflammation, infection, or trauma to the body.

Diphtheria—A serious, often fatal, bacterial infection that produces a toxin (poison) and an inflammation in the membrane lining of the throat, nose, trachea, and other tissues.

Epiglottitis—A bacterial infection that affects the epiglottis. The epiglottis is a flap of tissue that prevents food and fluid from entering the trachea. The infection causes it to become swollen, potentially blocking the airway. Other symptoms include a high fever, muffled voice, and an inability to swallow properly (possibly indicated by drooling).

Larynx—Also known as the voice box, the larynx is the part of the airway that lies between the pharynx and the trachea. It is composed of cartilage that contains the apparatus for voice production—the vocal cords and the muscles and ligaments that move the cords.

Reye's syndrome—A rare but often fatal disease that involves the brain, liver, and kidneys. It may brought on by giving salicylates (aspirin compounds) to children (but not adults) who have a viral infection.

Stridor—The high-pitched or rasping noise made when air is inhaled through narrowed airways.

Trachea—Commonly called the windpipe, it is the air pathway that connects the nose and mouth to the lungs.

cough may be preceded by one to three days of symptoms that resemble a slight cold. A croupy cough is often accompanied by a runny nose, hoarseness, and a low **fever**. When the child inhales, there may be a raspy or high-pitched noise called **stridor**, owing to the narrowed airway and accumulated mucus. In the presence of stridor, medical attention is required. However, the airway rarely narrows so much that breathing is impeded. Symptoms usually go away completely within a few days. Medical treatment may be sought if the child's symptoms do not respond to home treatment.

Emergency medical treatment is required immediately if the child has difficulty breathing, swallowing, or talking; develops a high fever (103°F [39.4°C] or more); seems unalert or confused; or has pale or blue-tinged skin.

Diagnosis

Croup is diagnosed based on the symptoms. If symptoms are particularly severe, or do not respond to treatment, an x ray of the throat area may be done to assess the possibility of epiglottitis or other blockage of the airway.

Treatment

Home remedies

Home treatment is the usual method of managing croup symptoms. It is important that the child is kept comfortable and calm to the best degree possible, because crying can make symptoms seem worse. Humid air can help a child with croup feel more comfortable. Recommended methods include sitting in a steamy bathroom with the hot water running or using a cool-water vaporizer or humidifier. However, although cool-mist therapy at home or in the hospital may add to the child's comfort, it does little to treat the actual condition. The child should drink frequently in order to stay well hydrated. To treat any fever, the child may be given an appropriate dose of **acetaminophen** (like Tylenol). Children should not be given **aspirin**, as it may cause Reye's syndrome, a life-threatening disease of the brain. **Antihistamines** and **decongestants** are ineffective in treating croup.

Medical treatment

If the child does not respond to home treatment, medical treatment at a doctor's office or an emergency room could be necessary. Based on the severity of symptoms and the response to treatment, the child may need to be admitted to a hospital.

For immediate symptom relief, epinephrine may be administered as an inhaled aerosol. Effects last for up to two hours, but there is a possibility that symptoms may return. For that reason, the child is kept under supervision for three or more hours. **Steroids** (**corticosteroids**) such as prednisone may be used to

WWW.BOOKBAZ.IR

treat croup, particularly if the child has stridor when resting.

Of the 1–5% of children requiring medical treatment, approximately 1% need respiratory support. Such support involves intubation (inserting a tube into the trachea) and oxygen administration.

Alternatives

Botanical/herbal medicines can be helpful in healing the cough that is commonly associated with croup. Several herbs to consider for cough treatment include aniseed (*Pimpinella anisum*), sundew (*Drosera rotundifolia*), thyme (*Thymus vulgaris*), and wild cherry bark (*Prunus serotina*). **Homeopathic medicine** can be very effective in treating cases of croup. Choosing the correct remedy (a common choice is aconite or monkshood, *Aconitum napellus*) is always the key to the success of this type of treatment.

Prognosis

Croup is a temporary condition and children typically recover completely within three to six days. Children can experience one or more episodes of croup during early childhood; however, croup is rarely a dangerous condition.

Prevention

Croup is caused by highly transmissible viruses and is often difficult to impossible to prevent.

Cryoglobulin test

Definition

Cryoglobulin is an abnormal blood protein associated with several diseases. Testing for cryoglobulin is done when a person has symptoms of this protein or is being evaluated for one of the associated diseases.

Purpose

Cryoglobulin clumps in cold temperatures. This physical characteristic causes people with cryoglobulin to have symptoms during cold weather: blanching, numbness, and **pain** in their fingers or toes (Raynaud's phenomenon); bleeding into the skin (purpura); and pain in joints (arthralgia). People with these symptoms or any other symptoms that appear in cold weather should be tested for cryoglobulin.

Diseases that cause the body to make extra or abnormal proteins are often associated with cryoglobulin. These diseases include cancers involving white blood cells, infections, **autoimmune disorders**, and rheumatoid diseases.

This test provides information about the cause of symptoms in a person who already has a disease process. It does not diagnose a specific disease or monitor the course of a disease.

Precautions

This test is not a screening test for disease in a person without symptoms.

Description

Laboratory testing for cryoglobulin is based on the fact that cryoglobulin clumps when cooled and dissolves when warmed. The test is done on a person's serum (the yellow liquid part of blood that separates from the cells after the **blood clots**). The serum is kept warm from the time drawn until the cells and the serum are separated in the laboratory. The serum is placed at 33.8°F (1°C) for one to seven days. If there is clumping, cryoglobulins are present. The amount of cryoglobulins is determined by measuring the amount of clumping. Negative tests are checked through seven days.

Additional testing is done to find out what kind of cryoglobulin protein is present. There are three kinds of cryoglobulin, each associated with different diseases.

KEY TERMS

Cryoglobulin—An abnormal blood protein associated with several diseases. It is characterized by its tendency to clump in cold temperatures.

The test, also called the cold sensitivity antibodies test, is covered by insurance when medically necessary. Results are usually available the following day.

Preparation

This test requires 15–20 mL of blood. A healthcare worker ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes. The blood must be kept warm, at body temperature, until the laboratory can separate the cells from the serum.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Results

A normal result will be negative or absent.

If the person has cryoglobulin, the amount is reported. Larger amounts of cryoglobulin are associated with cancers or abnormalities involving white blood cells, moderate amounts are associated with autoimmune disorders and rheumatoid diseases, and smaller amounts are associated with infections.

The type of cryoglobulin is also reported. Type I cryoglobulin, also called monoclonal cryoglobulinemia, is found in cancers or abnormalities of white blood cells. Type II, also called mixed cryoglobulinemia, is associated with autoimmune disorders, rheumatoid diseases, and infections, particularly chronic **hepatitis B**.

The physician must interpret the cryoglobulin result along with other test results and the patient's clinical condition and medical history.

Cryosurgery *see* **Cryotherapy**

Cryotherapy

Definition

Cryotherapy is a technique that uses an extremely cold liquid or instrument to freeze and destroy abnormal skin cells that require removal. The technique has been in use since the turn of the century, but modern techniques have made it widely available to dermatologists and primary care doctors. The technique is also called cryosurgery.

Purpose

Cryotherapy can be employed to destroy a variety of benign skin growths, such as **warts**, pre-cancerous lesions (such as actinic keratoses), and malignant lesions (such as basal cell and squamous cell cancers). The goal of cryotherapy is to freeze and destroy targeted skin growths while preserving the surrounding skin from injury.

Precautions

Cryotherapy is not recommended for certain areas of the body because of the danger of destruction of tissue or unacceptable scarring. These areas include: skin that overlies nerves, the corners of the eyes, the fold of skin between the nose and lip, the skin surrounding the nostrils, and the border between the lips and the rest of the face. Lesions that are suspected or known to be malignant **melanoma** should not be treated with cryotherapy, but should instead be removed surgically. Similarly, basal cell or squamous cell carcinomas that have reappeared at the site of a previously treated tumor should also be removed surgically. If it remains unclear whether a growth is benign or malignant, a sample of tissue should be removed for analysis (biopsy) by a pathologist before any attempts to destroy the lesion with cryotherapy. Care should be taken in people with diabetes or certain circulation problems when cryotherapy is considered for growths located on their lower legs, ankles, and

WWW.BOOKBAZ.IR

KEY TERMS

Actinic keratosis—A crusty, scaly pre-cancerous skin lesion caused by damage from the sun. Frequently treated with cryotherapy.

Basal cell cancer—The most common form of skin cancer; it usually appears as one or several nodules having a central depression. It rarely spreads (metastisizes), but is locally invasive.

Cryogen—A substance with a very low boiling point, such as liquid nitrogen, used in cryotherapy treatment.

Melanoma—The most dangerous form of skin cancer. It should not be treated with cryotherapy, but should be removed surgically instead.

Squamous cell cancer—A form of skin cancer that usually originates in sun-damaged areas or pre-existing lesions; at first local and superficial, it may later spread to other areas of the body.

feet. In these patients, healing can be poor and the risk of infection can be higher than for other patients.

Description

There are three main techniques to performing cryotherapy. In the simplest technique, usually reserved for warts and other benign skin growths, the physician will dip a cotton swab or other applicator into a cup containing a "cryogen," such as liquid nitrogen, and apply it directly to the skin growth to freeze it. At a temperature of −320°F (−196°C), liquid nitrogen is the coldest cryogen available. The goal is to freeze the skin growth as quickly as possible, and then let it thaw slowly to cause maximum destruction of the skin cells. A second application may be necessary depending on the size of the growth. In another cryotherapy technique, a device is used to direct a small spray of liquid nitrogen or other cryogen directly onto the skin growth. Freezing may last from five to 20 seconds, depending on the size of the lesion. A second freeze-thaw cycle may be required. Sometimes, the physician will insert a small needle connected to a thermometer into the lesion to make certain the lesion is cooled to a low enough temperature to guarantee maximum destruction. In a third option, liquid nitrogen or another cryogen is circulated through a probe to cool it to low temperatures. The probe is then brought into direct contact with the skin lesion to freeze it. The freeze time can take two to three times longer than with the spray technique.

Preparation

Extensive preparation prior to cryotherapy is not required. The area to be treated should be clean and dry, but sterile preparation is not necessary. Patients should know that they will experience some **pain** at the time of the freezing, but local **anesthesia** is usually not required. The physician may want to reduce the size of certain growths, such as warts, prior to the cryotherapy procedure, and may have patients apply salicylic acid preparations to the growth over several weeks. Sometimes, the physician will pare away some of the tissue using a device called a curette or a scalpel.

Aftercare

Redness, swelling, and the formation of a blister at the site of cryotherapy are all expected results of the treatment. A gauze dressing is applied and patients should wash the site three or four times daily while fluid continues to ooze from the wound, usually for 5–14 days. A dry crust then forms that falls off by itself. **Wounds** on the head and neck may take four to six weeks to heal, but those on the body, arms, and legs can take longer. Some patients experience pain at the site following the treatment. This can usually be eased with **acetaminophen** (Tylenol), though in some cases a stronger pain reliever may be required.

Risks

Cryotherapy poses little risk and can be well-tolerated by elderly and other patients who are not good candidates for other surgical procedures. As with other surgical procedures, there is some risk of scarring, infection, and damage to underlying skin and tissue. These risks are generally minimal in the hands of experienced users of cryotherapy.

Results

Some redness, swelling, blistering and oozing of fluid are all common results of cryotherapy. Healing time can vary by the site treated and the cryotherapy technique used. When cryogen is applied directly to the growth, healing may occur in three weeks. Growths treated on the head and neck with the spray technique may take four to six weeks to heal; growths treated on other areas of the body may take considerably longer. Cryotherapy boasts high success rates in permanently removing skin growths; even for malignant lesions such as squamous cell and basal

cell cancers, studies have shown a cure rate of up to 98%. For certain types of growths, such as some forms of warts, repeat treatments over several weeks are necessary to prevent the growth's return.

Abnormal results

Although cryotherapy is a relatively low risk procedure, some side effects may occur as a result of the treatment. They include:

- Infection. Though uncommon, infection is more likely on the lower legs where healing can take several months.
- Pigmentary changes. Both hypopigmentation (lightening of the skin) and hyperpigmentation (darkening of the skin) are possible after cryotherapy. Both generally last a few months, but can be longer lasting.
- Nerve damage. Though rare, damage to nerves is possible, particularly in areas where they lie closer to the surface of the skin, such as the fingers, the wrist, and the area behind the ear. Reports suggest this will disappear within several months.

Richard H. Camer

Cryptococcosis

Definition

Cryptococcosis is an infection caused by inhaling the fungus *Cryptococcus neoformans*. It is one of the diseases most often affecting **AIDS** patients. Cryptococcosis may be limited to the lungs, but frequently spreads throughout the body. Although almost any organ can be infected, the fungus is often fatal if it infects the nervous system where it causes an inflammation of the membranes covering the brain and spinal cord (**meningitis**).

Description

The fungus causing cryptococcis, *C. neoformans*, is found worldwide in soil contaminated with pigeon or other bird droppings. It has also been found on unwashed raw fruit. Cryptococcosis is a rare disease in healthy individuals, but is the most common fungal infection affecting people with AIDS.

This lesion appearing on this person's body is due to exposure of the *C. neoformans* fungus. *(Photo Researchers, Inc.)*

People with Hodgkin's disease or who are taking large doses of drugs that suppress the functioning of the immune system (**corticosteroids**, **chemotherapy** drugs) are also more susceptible to cryptococcal infection. Cryptococcosis is also called cryptococcal meningitis (when the brain is infected), Busse-Buschke disease, European **blastomycosis**, torular meningitis, or torulosis.

Causes and symptoms

Once the cryptococcal fungus reaches the lungs, three things can happen. The immune system can heal the body without medical intervention, the disease can stay localized in the lungs, or it can spread throughout the body. In healthy people with normally functioning immune systems, the body usually heals itself, and the infected person notices no symptoms and has no complications (asymptomatic). The disease does not spread from one person to another.

Cryptococcosis is an opportunistic infection that puts people with immune system diseases at higher risk of developing more serious forms of the disease. In the United States, 6–10% of all patients with AIDS get cryptococcosis.

If the body does not heal itself, the fungus begins to grow in the lungs and form nodules that can be seen on chest x rays. In the early stages of infection, an individual usually only exhibits symptoms of a respiratory infection, such as a dry **cough**, so the disease is rarely diagnosed.

WWW.BOOKBAZ.IR

The fungus can remain dormant in the lungs and produce an active infection later if the immune system is weakened. If the disease becomes active, it can cause cryptococcal **pneumonia** in the lungs. Unfortunately, however, cryptococcal pneumonia has symptoms similar to other pneumonias (cough, chest **pain**, difficulty breathing), making it difficult to accurately diagnose. The infection can spread to other parts of the body, particularly the brain and central nervous system.

Most patients are not diagnosed as having cryptococcosis until they show signs of cryptococcal meningitis, or infection of the membranes surrounding the brain and spinal cord. Symptoms appear gradually over a period of two to four weeks. **Fever** and **headache** are the most common symptoms, occurring in about 85% of patients. Nausea, **vomiting**, unwanted weight loss, and **fatigue** are also common. Other symptoms seen in 25–30% of patients are blurred vision, stiff neck, aversion to light, and seizures. Since the symptoms of classic meningitis, such as stiff neck and aversion to light, do not occur in many patients, diagnosis is often delayed. In addition to meningitis, inflammation of the brain (encephalitis) and brain lesions called cryptococcomas or tortulomas can also develop.

In addition to the brain, the cryptococcal infection can spread to the kidneys, bone marrow, heart, adrenal glands, lymph nodes, urinary tract, blood, and skin. Often times preceding the development of cryptococcal meningitis, painless **rashes** and lesions that mimic other skin diseases, such as *molluscum contagiosum*, may develop. A small percentage of patients with brain infections show infections in other organs as well.

Diagnosis

Physicians who regularly work with AIDS patients have the most experience in diagnosing cryptococcosis. The preferred methods of diagnosis use simple and very accurate blood and cerebrospinal fluid (CSF) tests that detect the presence of an antigen produced by the fungus. The cerebrospinal fluid test is generally more sensitive to detecting the meningitis form of the infection. CSF is collected during a procedure called a **lumbar puncture**, during which an anesthetic is applied to a small area of the back near the spine and a needle is used to withdraw a sample of cerebrospinal fluid from the space between the vertebrae and the spinal cord. Once obtained, a small amount of ink (called India ink) is added to a sample of CSF or a sample prepared from **skin lesions**. If the fungus is present, it will become visible when the ink binds to the capsule or covering that surrounds the fungus. Faster results are obtained with the India ink test, but it is less accurate than the blood test (75–85% accuracy compared to 99% accuracy with the blood test) because some strains are not visible using this method. Antigen tests are routinely recommended for non-symptomatic patients with advanced AIDS.

Another way to diagnose cryptococcosis is to culture a sample of sputum, tissue from a **lung biopsy**, or CSF in the laboratory to isolate the fungus. Cultures are also done to assess the effectiveness of treatment.

Chest x rays are useful in assessing lung damage and may reveal a single mass or multiple distinct nodules, but the x ray alone does not lead to a definitive diagnosis of cryptococcosis.

Treatment

Once cryptococcosis is diagnosed, treatment begins with amphotericin B (Fungizone), sometimes in combination with 5-flucytosine (Ancobon). Amphotericin B is a powerful fungistatic drug with potentially toxic side effects, such as kidney toxicity and lower concentrations of an important blood component called hemoglobin. This medication can also cause fever, chills, **nausea and vomiting**, **diarrhea**, headache, and muscle aches. Treatment is generally given intravenously during a hospital stay and continues until the patient is stable or improving (no more than two to three weeks). 5-flucytosine is given orally. Patients may also receive other medication to minimize the side effects from these drugs.

Amphotericin B, with or without 5-flucytosine, is given for several weeks until the patient is stable, after which the patient receives oral fluconazole (Diflucan). Fluconazole is a broad-spectrum antifungal drug with few serious side effects. Patients with AIDS must continue taking fluconazole for the rest of their lives to prevent a relapse of cryptococcosis. Sometimes fluconazole is given to patients with advanced AIDS as a preventative (prophylactic) measure.

Because of the high cost of fluconazole, the manufacturer of the drug, Pfizer, has established a financial assistance plan to make the drug available at lower cost to those who meet certain criteria. Patients needing this drug should ask their doctors about this program.

Prognosis

Untreated cryptococcosis is always fatal. The acute mortality rate for patients with AIDS is

KEY TERMS

Adrenal gland—A pair of organs located above the kidneys. The outer tissue of the gland produces the hormones epinephrine (adrenaline) and norepinephrine, while the inner tissue produces several steroid hormones.

Amphotericin B (Fengizone)—An antifungal medication, prescribed for topical or systemic use in treating fungal infections.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—A foreign protein or particle capable of eliciting an immune response.

Asymptomatic—Persons who carry a disease but who do not exhibit symptoms of the disease are said to be asymptomatic.

Biopsy—The removal of a tissue sample for diagnostic purposes.

Cerebrospinal fluid (CSF)—The clear fluid that surrounds the spinal cord and brain and acts as a shock absorber.

Corticosteroids—A group of hormones produced naturally by the adrenal gland or manufactured synthetically. They are often used to treat inflammation. Examples include cortisone and prednisone.

Encephalitis—Inflammation of the brain.

Hodgkin's disease—A disease that causes chronic inflammation of the lymph nodes, spleen, liver and kidneys. It is also called malignant lymphoma.

Hydrocephalus—Build-up of fluid around the brain.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

India ink test—A diagnostic test used to detect the cryptococcal organism *C. neoformans*. A dye, called India ink, is added to a sample of CSF fluid, and if the fungi is present, they will become visible as the dye binds to the capsule surrounding the fungus.

Lumbar puncture—Also called a spinal tap, a procedure in which a thin needle is used to withdraw a sample of cerebrospinal fluid for diagnostic purposes from the area surrounding the spine.

Meningitis—Inflammation of the membranes covering the brain and spinal cord called the meninges.

Molluscum contagiosum—A disease of the skin and mucuous membranes, caused by a poxvirus and found all over the world.

Opportunistic infection—An infection that is normally mild in a healthy individual, but which takes advantage of an ill person's weakened immune system to move into the body, grow, spread, and cause serious illness.

Pneumonia—Inflammation of the lungs, typically caused by a virus, bacteria, or other organism.

10–25%. Most deaths are attributable to cryptococcal meningitis and occur within two weeks after diagnosis. For AIDS patients who do not receive continued suppressive therapy (fluconazole), the relapse rate is 50–60% within six months and a shortened life expectancy. Once the cryptococcosis infection has been successfully treated, individuals may be left with a variety of neurologic symptoms, such as weakness, headache, and hearing or visual loss. In addition, fluid may accumulate around the brain (**hydrocephalus**).

Prevention

The best way to prevent cryptococcosis is to stay free of HIV infection. People with suppressed immune systems should try to stay away from areas contaminated with pigeon or other bird droppings, such as the attics of old buildings, barns, and areas under bridges where pigeons roost.

Cryptosporidiosis

Definition

Cryptosporidiosis refers to infection by the spore-forming protozoan known as *Cryptosporidia*. Protozoa are a group of parasites that infect the human intestine, and include the better known *Giardia*. *Cryptosporidia* was first identified in 1976 as a cause of disease in humans.

Description

Cryptosporidia are normally passed in the feces of infected persons and animals in the form of cysts. The cysts can remain in the ground and water for months, and when ingested produce symptoms after maturing in the intestine and the bile ducts. When viewed under the microscope, they appear as small bluish-staining round bodies. Most common sources of infection are other humans, water supplies, or reservoirs. These are contaminated by animals that defecate in these areas. An outbreak in Milwaukee in 1993 in which over 400,000 persons were affected was traced to the city's water supply. Cysts of *Cryptosporidia* are extremely resistant to the disinfectants that are commonly used in most water treatment plants and are incompletely removed by filtration.

Most persons who experience significant symptoms have an altered immune system, and suffer from diseases such as **AIDS** and cancer. However, as shown in the Milwaukee outbreak, even those with normal immunity can experience symptoms.

Causes and symptoms

Cysts of *Cryptosporidia* mature in the intestine and bile ducts within three to five days of ingestion. As noted, large-scale infections from contaminated water supplies has been documented. However, human to human transmission (such as occurs in day care centers or through sexual behavior) is also an important cause.

Many individuals can be infected without any illness, but the major symptom is **diarrhea**, which is often watery and incapacitating. **Dehydration**, low-grade **fever**, nausea, and abdominal cramps are frequent.

In those with a normal immune system, the disease usually lasts about 10 days. For patients with altered immunity (immunocompromised), the story is quite different, with diarrhea becoming chronic, debilitating, and even fatal.

Complications

Dehydration and **malnutrition** are the most common effects of infection. In about 20% of AIDS patients, bile duct infection also occurs and causes symptoms similar to gallbladder attacks. Eighty percent or more of those with infection of the bile ducts die from the disease. The lungs and pancreas are also sometimes involved. *Cryptosporidia* are just one cause of the diarrhea wasting syndrome in AIDS, which results in severe weight loss and malnutrition.

Diagnosis

This is based on either finding the characteristic cysts in stool specimens, or on biopsy of an infected organ, such as the intestine.

Treatment

The first aim of treatment is to avoid dehydration. Oral Rehydration Solution (ORS) or intravenous fluids may be needed. Medications used to treat diarrhea by decreasing intestinal motility (Anti-Motility Agents), such as loperamide or diphenoxylate, are also useful, but should only be used with the advice of a physician.

Treatment aimed directly at *Cryptosporidia* is only partially effective, and rarely eliminates the organism. The medication most commonly used is paromomycin (Humatin), but others are presently under evaluation.

Prognosis

Cryptosporidia rarely cause a serious disease in persons with normal immune systems. Replacement of fluids is all that is usually needed. On the other hand, those with altered immune systems often suffer for months to years. Paramomycin and other drugs have been able to improve symptoms in over half of those treated. Unfortunately, many organisms are resistant, and recurrence is frequent.

Prevention

The best way to prevent cryptosporidiosis is to minimize exposure to cysts from infected humans and animals. Proper hand washing technique, especially in day care centers, is recommended.

KEY TERMS

Anti-motility medications—Medications such as loperamide (sold as Imodium), dephenoxylate (sold as Lomotil), or medications containing codeine or narcotics that decrease the ability of the intestine to contract. This can worsen the condition of a patient with dysentery or colitis.

Cyst—A protective sac that includes either fluid or the cell of an organism. The cyst enables many organisms to survive in the environment for long periods of time without need for food or water.

Immunocompromised—A change or alteration of the immune system that normally serves to fight off infections and other illnesses. This can involve changes in antibodies that the body produces (hygogammaglobulinemia), or defect in the cells that partake in the immune response. Diseases such as AIDS and cancer exhibit changes in the body's natural immunity.

Oral Rehydration Solution (ORS)—A liquid preparation developed by the World Health Organization that can decrease fluid loss in persons with diarrhea. Originally developed to be prepared with materials available in the home, commercial preparations have recently come into use.

Parasite—An organism that lives on or in another and takes nourishment (food and fluids) from that organism.

Protozoa—Group of extremely small single cell (unicellular) or acellular organisms that are found in moist soil or water. They tend to exist as parasites, living off other life forms.

Spore—A resistant form of certain species of bacteria, protozoa, and other organisms.

CT-guided biopsy

Definition

Computed tomography (CT) is a process that images anatomic information from a cross-sectional plane of the body. Biopsy is the process of taking a sample of tissue from the body for analysis. CT is commonly used in biopsies to provide images that help guide the tools or equipment necessary to perform the biopsy to the appropriate area of the body.

Purpose

CT is used in the process of performing a biopsy, such as a needle biopsy, in order to guide the needle to the site of the biopsy and to provide rapid and precise localization of the needle. CT enables imaging of areas that are normally beyond visible boundaries. This enables the physician to see the target area clearly and help to ensure that the tissue being removed is from the target lesion.

Precautions

The patient that suffers from claustrophobia will want to discuss this with their physician. This procedure involves the patient being placed into the CT scanner, typically a small, enclosed area. Depending on the specific type of biopsies being performed, certain anesthetics will be used, so discuss drug **allergies** with your physician.

Description

CT can assist in providing more enhanced images of a suspicious lesion. It helps to determine whether a tumor is truly solitary or not. CT can characterize the tumor and aid in the estimation of malignancy.

WWW.BOOKBAZ.IR

KEY TERMS

Lesion—A pathologic change in tissues.

Malignancy—A locally invasive and destructive growth.

Preparation

Since there are many different types of biopsies, you should follow the instructions from your physician to prepare for your CT-guided biopsy. Patients who are claustrophobic should discuss their concerns with the physician. In some cases, medicine can be given that will relax the patient during the procedure.

Risks

CT-guided biopsy does not increase the risk of the biopsy any more than any other radiologic imaging such as x ray.

Results

Because the area being biopsied, as well as the specific type of biopsy procedure can vary, results will vary. Before undergoing the procedure, notification procedure should be clearly defined.

Culture-fair test

Definition

A culture-fair test is test designed to be free of cultural bias, as far as possible, so that no one culture has an advantage over another. The test is designed to not be influenced by verbal ability, cultural climate, or educational level.

Purpose

The purpose of a culture-fair test is to eliminate any social or cultural advantages, or disadvantages, that a person may have due to their upbringing. The test can be administered to anyone, from any nation, speaking any language. A culture-fair test may help identify learning or emotional problems. The duration of the test varies for the individual types of tests available, but the time is approximately between 12–18 minutes per section (a test usually has two to four sections).

A culture-fair test is often administered by employers in order to determine the best location for new employees in a large company. The wide variety of culture-fair tests available allows the administrator to select which area is most vital, whether it be general intelligence, knowledge of a specific area, or emotional stability.

Precautions

There is doubt as to whether any test can truly be culturally unbiased or can ever be made completely fair to all persons independent of culture. There are no other precautions.

Description

A culture-fair test is a non-verbal paper-pencil test that can be administered to patients as young as four years old. The patient only needs the ability to recognize shapes and figures and perceive their respective relationships. Some examples of tasks in the test may include:

- completing series
- classifying
- solving matrices
- evaluating conditions

The culture-fair test is also often referred to as a culture-free test or unbiased test. There are many variations of the test including class, economic, and intelligence tests. The threading theme among the various tests is their design to be culturally unbiased.

Preparation

The only preparation necessary to administer the test is pre-ordered materials and a quiet and secluded location for the duration of the test.

Aftercare

Post-test treatment depends on the results of the test and the specifics of the individual patient. Any further treatment is best prescribed by the doctor.

Risks

There are no risks associated with the culture-fair test.

Results

The results can be compared to the key that comes with the purchase of a culture-fair test. All results should be compared to the included key.

Cushing's syndrome

Definition

Cushing's syndrome is a relatively rare endocrine (hormonal) disorder resulting from excessive exposure to the hormone cortisol. The disorder, which leads to a variety of symptoms and physical abnormalities, is most commonly caused by taking medications containing the hormone over a long period of time. A more rare form of the disorder occurs when the body itself produces an excessive amount of cortisol.

Description

The adrenals are two glands, each of which is perched on the upper part of the two kidneys. The outer part of the gland is known as the cortex; the inner part is known as the medulla. Each of these parts of the adrenal gland is responsible for producing different types of hormones. Regulation of hormone production and release from the adrenal cortex involves the pituitary gland, a small gland located at the base of the brain. After the hypothalamus (the part of the brain containing secretions important to metabolic activities) sends "releasing hormones" to the pituitary gland, the pituitary secretes a hormone called adrenocorticotropic hormone (ACTH). The ACTH then travels through the bloodstream to the adrenal cortex, where it encourages the production and release of cortisol (sometimes called the "stress" hormone) and other adrenocortical hormones.

Woman with Cushing's syndrome. *(Photo Researchers, Inc.)*

Cortisol, a very potent glucocorticoid—a group of adrenocortical hormones that protects the body from **stress** and affect protein and carbohydrate metabolism—is involved in regulating the functioning of nearly every type of organ and tissue in the body, and is considered to be one of the few hormones absolutely necessary for life. Cortisol is involved in:

- complex processing and utilization of many nutrients, including sugars (carbohydrates), fats, and proteins
- normal functioning of the circulatory system and the heart
- functioning of muscles

WWW.BOOKBAZ.IR

- normal kidney function
- production of blood cells
- normal processes involved in maintaining the skeletal system
- proper functioning of the brain and nerves
- normal responses of the immune system

Cushing's syndrome, also called hypercortisolism, has an adverse effect on all of the processes described above. The syndrome occurs in approximately 10 to 15 out of every 1 million people per year, usually striking adults between the ages of 20 and 50.

Causes and symptoms

The most common cause of Cushing's syndrome is the long-term use of glucocorticoid hormones in medications. Medications such as prednisone are used in a number of inflammatory conditions. Such conditions include **rheumatoid arthritis**, **asthma**, **vasculitis**, lupus, and a variety of other **autoimmune disorders** in which the body's immune cells accidentally attack some part of the body itself. In these disorders, the glucocorticoids are used to dampen the immune response, thereby decreasing damage to the body.

Cushing's syndrome can also be caused by three different categories of disease:

- a pituitary tumor producing abnormally large quantities of ACTH
- the abnormal production of ACTH by some source other than the pituitary
- a tumor within the adrenal gland overproducing cortisol

Although it is rare, about two-thirds of endogenous (occurring within the body rather than from a source outside the body, like a medication) Cushing's syndrome is caused by excessive secretion of ACTH by a pituitary tumor, usually an adenoma (noncancerous tumor). The pituitary tumor causes increased growth of the adrenal cortex (hyperplasia) and increased cortisol production. Cushing's disease affects women more often than men.

Tumors in locations other than the pituitary can also produce ACTH. This is called ectopic ACTH syndrome ("ectopic" refers to something existing out of its normal place). Tumors in the lung account for more than half of all cases of ectopic ACTH syndrome. Other types of tumors that may produce ACTH include tumors of the thymus, the pancreas, the thyroid, and the adrenal gland. Nearly all adrenal gland tumors are benign (noncancerous), although in rare instances a tumor may actually be cancerous.

Symptoms of cortisol excess (resulting from medication or from the body's excess production of the hormone) include:

- weight gain
- an abnormal accumulation of fatty pads in the face (creating the distinctive "moon face" of Cushing's syndrome); in the trunk (termed "truncal obesity"); and over the upper back and the back of the neck (giving the individual what has been called a "buffalo hump")
- purple and pink stretch marks across the abdomen and flanks
- high blood pressure
- weak, thinning bones (osteoporosis)
- weak muscles
- low energy
- thin, fragile skin, with a tendency toward both bruising and slow healing
- abnormalities in the processing of sugars (glucose), with occasional development of actual diabetes
- kidney stones
- increased risk of infections
- emotional disturbances, including mood swings, depression, irritability, confusion, or even a complete break with reality (psychosis)
- irregular menstrual periods in women
- decreased sex drive in men and difficulty maintaining an erection
- abormal hair growth in women (in a male pattern, such as in the beard and mustache area), as well as loss of hair from the head (receding hair line)

Diagnosis

Diagnosing Cushing's syndrome can be complex. Diagnosis must not only identify the cortisol excess, but also locate its source. Many of the symptoms can be attributed to numerous other diseases. Although a number of these symptoms seen together would certainly suggest Cushing's syndrome, the symptoms are still not specific to Cushing's syndrome. Following a review of the patient's medical history, **physical examination**, and routine blood tests, a series of more sophisticated tests is available to achieve a diagnosis.

24-hour free cortisol test

This is the most specific diagnostic test for identifying Cushing's syndrome. It involves measuring the amount of cortisol present in the urine over a 24-hour period. When excess cortisol is present in the

bloodstream, it is processed by the kidneys and removed as waste in the urine. This 24-hour free cortisol test requires that an individual collect exactly 24-hours' worth of urine in a single container. The urine is then analyzed in a laboratory to determine the quantity of cortisol present. This technique can also be paired with the administration of dexamethasone, which in a normal individual would cause urine cortisol to be very low. Once a diagnosis has been made using the 24-hour free cortisol test, other tests are used to find the exact location of the abnormality causing excess cortisol production.

Dexamethasone suppression test

This test is useful in distinguishing individuals with excess ACTH production due to a pituitary adenoma from those with ectopic ACTH-producing tumors. Patients are given dexamethasone (a synthetic glucocorticoid) orally every six hours for four days. Low doses of dexamethasone are given during the first two days; for the last two days, higher doses are administered. Before dexamethasone is administered, as well as on each day of the test, 24-hour urine collections are obtained.

Because cortisol and other glucocorticoids signal the pituitary to decrease ACTH, the normal response after taking dexamethasone is a drop in blood and urine cortisol levels. Thus, the cortisol response to dexamethasone differs depending on whether the cause of Cushing's syndrome is a pituitary adenoma or an ectopic ACTH-producing tumor.

The dexamethasone suppression test may produce false-positive results in patients with conditions such as depression, alcohol **abuse**, high estrogen levels, acute illness, and stress. On the other hand, drugs such as phenytoin and phenobarbital may produce false-negative results. Thus, patients are usually advised to stop taking these drugs at least one week prior to the test.

Corticotropin-releasing hormone (CRH) stimulation test

The CRH stimulation test is given to help distinguish between patients with pituitary adenomas and those with either ectopic ACTH syndrome or cortisol-secreting adrenal tumors. In this test, patients are given an injection of CRH, the corticotropin-releasing hormone that causes the pituitary to secrete ACTH. In patients with pituitary adenomas, blood levels of ACTH and cortisol usually rise. In patients with ectopic ACTH syndrome, this rise is rarely seen. In patients with cortisol-secreting adrenal tumors, this rise almost never occurs.

Petrosal sinus sampling

Although this test is not always necessary, it may be used to distinguish between a pituitary adenoma and an ectopic source of ACTH. Petrosal sinus sampling involves drawing blood directly from veins that drain the pituitary. This test, which is usually performed with local **anesthesia** and mild **sedation**, requires inserting tiny, flexible tubes (catheters) through a vein in the upper thigh or groin area. The catheters are then threaded up slowly until they reach veins in an area of the skull known as the petrosal sinuses. X rays are typically used to confirm the correct position of the catheters. Often CRH is also given during the test to increase the accuracy of results.

When blood tested from the petrosal sinuses reveals a higher ACTH level than blood drawn from a vein in the forearm, the likely diagnosis is a pituitary adenoma. When the two samples show similar levels of ACTH, the diagnosis indicates ectopic ACTH syndrome.

Radiologic imaging tests

Imaging tests such as **computed tomography scans** (CT) and **magnetic resonance imaging** (MRI) are only used to look at the pituitary and adrenal glands after a firm diagnosis has already been made. The presence of a pituitary or adrenal tumor does not necessarily guarantee that it is the source of increased ACTH production. Many healthy people with no symptoms or disease whatsoever have noncancerous tumors in the pituitary and adrenal glands. Thus, CT and MRI is often used to image the pituitary and adrenal glands in preparation for surgery.

Treatment

The choice of a specific treatment depends on the type of problem causing the cortisol excess. Pituitary and adrenal adenomas are usually removed surgically. Malignant adrenal tumors always require surgical removal.

Treatment of ectopic ACTH syndrome also involves removing all of the cancerous cells that are producing ACTH. This may be done through surgery, **chemotherapy** (using combinations of cancer-killing drugs), or **radiation therapy** (using x rays to kill cancer cells), depending on the type of cancer and how far it has spread. Radiation therapy may also be used on the pituitary (with or without surgery) for patients who cannot undergo surgery, or for patients whose surgery did not successfully decrease pituitary release of ACTH.

WWW.BOOKBAZ.IR

KEY TERMS

Adenoma—A type of noncancerous (benign) tumor that often involves the overgrowth of certain cells of the type normally found within glands.

Adrenocorticotropic hormone (ACTH)—A pituitary hormone that stimulates the cortex of the adrenal glands to produce adrenal cortical hormones.

Cortisol—A hormone secreted by the cortex of the adrenal gland. Cortisol regulates the function of nearly every organ and tissue in the body.

Ectopic—In an abnormal position.

Endocrine—Pertaining to a gland that secretes directly into the bloodstream.

Gland—A collection of cells whose function is to release certain chemicals (hormones) that are important to the functioning of other, sometimes distantly located, organs or body systems.

Glucocorticoids—General class of adrenal cortical hormones that are mainly active in protecting against stress and in protein and carbohydrate metabolism.

Hormone—A chemical produced in one part of the body that travels to another part of the body in order to exert its effect.

Hypothalamus—the part of the brain containing secretions important to metabolic activities.

Pituitary—A gland located at the base of the brain, the pituitary produces a number of hormones, including hormones that regulate growth and reproductive function.

There are a number of drugs that are effective in decreasing adrenal production of cortisol. These medications include mitotane, ketoconazole, metyrapone, trilostane, aminoglutethimide, and **mifepristone**. These drugs are sometimes given prior to surgery in an effort to reverse the problems brought on by cortisol excess. However, the drugs may also need to be administered after surgery (sometimes along with radiation treatments) in patients who continue to have excess pituitary production of ACTH.

Because pituitary surgery can cause ACTH levels to drop too low, some patients require short-term treatment with a cortisol-like medication after surgery. Patients who need adrenal surgery may also require glucocorticoid replacement. If the entire adrenal gland has been removed, the patient must take oral glucocorticoids for the rest of his or her life.

Prognosis

Prognosis depends on the source of the problem. When pituitary adenomas are identified as the source of increased ACTH leading to cortisol excess, about 80% of patients are cured by surgery. When cortisol excess is due to some other form of cancer, the prognosis depends on the type of cancer and the extent of its spread.

Cutaneous larva migrans

Definition

Cutaneous larvae migrans is a parasitic skin disease caused by a hookworm larvae that usually infests dogs, cats, and other animals. Humans can pick up the infection by walking barefoot on soil or beaches contaminated with animal feces.

Description

Cutaneous larvae migrans (also called "creeping eruption" or "ground itch") is found in southeastern and Gulf states, and in tropical developing countries.

The hookworms that cause the condition are small, round blood-sucking worms that infest about 700 million people around the world. Cutaneous larvae migrans occurs most often among children, those

Linear red rashes around a patient's knee caused by burrowing larvae of the dog hookworm *Ancylostoma braziliensis*. *(Custom Medical Stock Photo, Inc.)*

who crawl beneath raised buildings, and sunbathers who lie down on wet sand contaminated with hookworm larvae.

Causes and symptoms

After an animal passes feces that are infested with hookworm eggs, the eggs hatch into infective larvae that are able to penetrate human skin (even through solid material, such as a beach towel). The larvae are commonly found in shaded, moist, or sandy areas (such as beaches, a child's sandbox, or areas underneath a house), where they are easily picked up by bare feet or buttocks.

In minor infestations, there may be no symptoms at all. In more severe cases, a red elevation of the skin (papule) appears within a few hours after the larvae have penetrated the skin. This usually arises first in areas that are in contact with the soil, such as the feet, hands, and buttocks.

Between a few days and a few months after infection, the larvae begin to migrate beneath the skin, leaving extremely itchy red lines that may be accompanied by blisters. These red lines usually appear at the top of the sole of the foot or on the buttocks.

Tyically, the larvae travel through the bloodstream, to the lungs, and then migrate into the mouth where they are swallowed and attach to the small intestine lining. There they mature into adult worms. In cases where the larvae migrate through the lungs, they can produce anemia, **cough**, and **pneumonia**, in addition to the itchy rash.

KEY TERMS

Larvae—Immature forms of certain worms.

Diagnosis

The condition can be diagnosed by microscopic inspection of feces, which can reveal hookworm eggs. Visual inspection of the skin would reveal telltale itchy red lines and blisters.

Treatment

People without intestinal symptoms do not need treatment, since the worms will eventually die or be excreted. Thiabendazole or albendazole are used to treat the infestation. Mild infections can be treated by applying one of the drugs to the skin along the tracks and the normal skin surrounding the area. Thiabendazole also can be given internally, but taken this way it can cause side effects including **dizziness**, nausea, and **vomiting**

Prognosis

No matter how severe an infestation, with adequate treatment patients recover completely. However, if the patient scratches the lesions open, the areas can become vulnerable to bacterial infection.

Prevention

In the United States, the prevalence of dogs and cats with hookworms is the reason why the infective larvae are found so commonly in soil and sand. The play habits of children, together with their attraction to pets, puts them at high risk for hookworm infection and cutaneous larvae migrans.

Human hookworm infestation can be prevented by practicing good personal hygiene, deworming pets, and not allowing children to play in potentially contaminated environments.

Cutaneous T-cell lymphoma

Definition

Cutaneous T-cell lymphoma (CTCL) is a malignancy of the T-helper (CD4+) cells of the immune system.

Description

CTCL, also known as mycosis fungoides, is a cancer of the white blood cells that primarily affects the skin and only secondarily affects other sites. This disease involves the uncontrollable proliferation of T-lymphocytes known as T-helper cells, so named because of their role in the immune response. T-helper cells are characterized by the presence of a protein receptor on their surface called CD4. Accordingly, T-helper cells are said to be CD4+.

The proliferation of T-helper cells results in the penetration, or infiltration, of these abnormal cells into the epidermal layer of the skin. The skin reacts with slightly scaling lesions that itch, although the sites of greatest infiltration do not necessarily correspond to the sites of the lesions. The lesions are most often located on the trunk, but can be present on any part of the body. In the most common course of the disease, the patchy lesions progress to palpable plaques that are deeper red and have more defined edges. As the disease worsens, skin tumors develop that are often mushroom-shaped, hence the name mycosis fungoides. Finally, the cancer progresses to extracutanous involvement, often in the lymph nodes or the viscera.

CTCL is a rare disease, with an annual incidence of about 0.29 cases per 100,000 persons in the United States. It is about half as common in Eastern Europe. However, this discrepancy may be attributed to a differing physician awareness of the disease rather than a true difference in occurrence. In the United States, there are about 500–600 new cases a year and about 100–200 deaths. CTCL is usually seen in older adults; the median age at diagnosis is 55–60 years. It strikes twice as many men as women. The average life expectancy at diagnosis is 7–10 years, even without treatment.

Causes and symptoms

The cause of CTCL is unknown. Exposure to chemicals or pesticides has been suggested; however, the most recent study on the subject failed to show a connection between exposure and development of the disease. The ability to isolate various viruses from cell lines grown from cells of CTCL patients raises the question of a viral cause, but studies have been unable to confirm these suspicions.

The symptoms of CTCL are seen primarily in the skin, with itchy red patches or plaques and, usually over time, mushroom-shaped skin tumors. Any part of the skin can be involved and the extent and distribution of the rash or tumors vary greatly from patient to patient. The only really universal symptom of the disease is the itch and this symptom is usually what brings the patient to the doctor for treatment. If the disease spreads outside of the skin, the symptoms include swelling of the lymph nodes, usually most severe in those draining the areas with skin involvement. Spread to the viscera is most often manifested as disorders of the lungs, upper digestive tract, central nervous system, or liver but virtually any organ can be shown to be involved at **autopsy**.

Some patients with CTCL develop a leukemic phase of the disorder known as Sézary syndrome, which is characterized by the appearance of malignant T cells in the bloodstream. It is named for the French dermatologist who first identified the abnormal T cells.

Diagnosis

Diagnosis of CTCL is often difficult in the early stages because of its slow progression and ability to mimic many other benign skin conditions. The early patches of CTCL resemble **eczema**, **psoriasis**, and **contact dermatitis**. In a further complication, the early manifestations of the disease can respond favorably to the topical corticosteroid treatments prescribed for these skin disorders. This has the unfortunate result of the disease being missed and the patient remaining untreated for years. CTCL is most likely discovered when a physician maintains a suspicion about the disease, performs multiple skin biopsies, and provides close follow-up after the initial presentation.

Skin biopsies showing penetration of abnormal cells into the epidermal tissue are necessary to make a firm diagnosis of CTCL. Several molecular studies can also help support the diagnosis. The first looks at the cellular proteins seen on the surface of the abnormal cells. Many cases of CTCL show the retention of the CD4+ protein, but the loss of other proteins usually seen on the surface of mature CD4+ cells, such as Leu-8 or Leu-9. The abnormal cells also show unusual rearrangements at the genetic level for the gene that encodes the T-cell receptors. These rearrangements can be identified using Southern blot analysis. The information from the molecular tests,

combined with the presence of abnormal cells in the epidermis, strongly supports the CTCL diagnosis.

Treatment

Treatment of CTCL depends on the stage of the disease. The current staging of this disease was first presented at the International Consensus Conference on CTCL in 1997. The staging attempts to show the complex interaction between the various outward symptoms of the disease and prognosis. The system has seven clinical stages based on skin involvement (tumor = T), lymph node involvement (LN), and presence of visceral metastases (M).

The first stage, IA, is characterized by plaques covering less than 10% of the body (T1) and no visceral involvement (M0). Lymph node condition at this stage can be uninvolved, reactive to the skin disease, or dermatopathic (biopsies showing CTCL involvement) but not enlarged (LN0-2). The shorthand expression of this stage is therefore T1, LN0-2, M0. The next stage, IB, differs from IA in that greater than 10% of the body is covered by plaques (T2, LN0-2, M0). Stage IIA occurs with any amount of plaques in addition to the ability to palpate the lymph node and the lymph uninvolved, reactive, or dermatopathic (T1-2, LN0-2, M0).

Treatments applied to the skin are preferred for patients having these preliminary stages of the disease, commonly topical **chemotherapy** with mechlorethamine hydrochloride (nitrogen mustard) or **phototherapy** of psoralen plus ultraviolet A (PUVA). Topical chemotherapy involves application to the skin of nitrogen mustard, an alkylating agent, in a concentration of 10–20 mg/dL in an aqueous or ointment base. Treatment of affected skin is suggested at a minimum and application over the entire skin surface is often recommended. Care needs to be taken that coverage of involved skin is adequate, as patients who self-apply the drug often cannot reach all affected areas. The most common side effect is skin hypersensitivity to the drug. Nearly all patients respond favorably to this treatment, with a 32–61% complete response rate, based on amount of skin involvement. Unfortunately, only 10–15% of patients maintain a complete response rate after discontinuing the treatment.

Phototherapy involves treatment with an orally administered drug, 8-methyloxypsoralen, that renders the skin sensitive to long-wave ultraviolet light (UVA), followed by controlled exposure to the radiation. During the initial treatment period, which may last as long as six months, patients are treated two to three times weekly. This is reduced to about once monthly after initial clearing of the lesions. Redness of the skin and blistering are the most common side effects of the treatment and are much more common in patients presenting with overall skin redness, or erythroderma, so lower intensities of light are usually used in this case. About 50% of all patients experience complete clearance with this treatment. Some patients with very fair skin and limited skin involvement can successfully treat themselves at home with special lamps and no psoralen.

The next stage, IIB, involves one or more cutaneous tumors, in combination with absent or present palpable lymph nodes, lymph uninvolved, reactive, or dermatopathic, and no visceral involvement (T3, LN0-2, M0). Stage III is characterized by erythroderma, an abnormal redness over widespread areas of the skin (T4, LN0-2, M0).

For more extensive disease, **radiation therapy** is an effective treatment option. It is generally used after the topical treatments have proven ineffective. Individual plaques or tumors can be treated using electrons, orthovoltage x rays, or megavoltage photons with exposure in the range of 15–25 Gy. Photon therapy has proven particularly useful once the lymph nodes are involved. Another possibility is total-skin electron beam therapy (TSEB), although the availability of this treatment method is limited. It involves irradiation of the entire body with energized electrons. Side effects of this treatment include loss of finger and toe nails, acute redness of the skin, and inability to sweat for about six to 12 months after therapy. Almost all patients respond favorably to radiation treatment and any reoccurrence is usually much less severe.

Combination of different types of treatments is a very common approach to the management of CTCL. Topical nitrogen mustard or PUVA is often used after completion of radiation treatment to prolong the effects. The addition of genetically engineered interferon to PUVA therapy significantly increases the percentage of patients showing a complete response. Furthermore, although treatments using chemotherapy drugs alone, such as deoxycofomycin or etretinate, have been disappointing for CTCL, combining these drugs with interferon has shown promising results. Interferon has also been combined with retinoid treatments, although the mechanism of action of retinoids (**Vitamin A** analogues) against CTCL is unknown.

The final two stages of the disease are IVA and IVB. IVA presents as any amount of skin involvement, absent or present palpable lymph nodes, no visceral

WWW.BOOKBAZ.IR

KEY TERMS

Alkylating agent—A chemical that alters the composition of the genetic material of rapidly dividing cells, such as cancer cells, causing selective cell death; used as a topical chemotherapeutic agent to treat CTCL.

Cutaneous—Pertaining to the skin.

Erythroderma—An abnormal reddening of the entire skin surface.

Monoclonal antibody—An antibody produced by the identical offspring of a single cloned antibody-producing cell.

Mycosis fungoides—Another name for cutaneous T-cell lymphoma.

Sézary syndrome—A leukemic phase of CTCL that develops in some patients, characterized by the appearance of malignant T cells in the peripheral blood and sometimes in the lymph nodes. The syndrome is named for Alfred Sézary (1880-1956), a French dermatologist.

T-helper cells—A cellular component of the immune system that plays a major role in ridding the body of bacteria and viruses, characterized by the presence of the CD4 protein on its surface; the type of cell that divides uncontrollable with CTCL.

Total-skin electron beam therapy—A method of radiation therapy used to treat CTCL that involves bombarding the entire body surface with high-energy electrons.

involvement, and lymph that contains large clusters of convoluted cells or obliterated nodes (T1-4, LN3-4). IVB differs in the addition of palpable lymph nodes and visceral involvement (T1-4, LN3-4, M1). All of the treatment methods described above are appropriate for the final two stages of the disease.

A newer drug that has been used to treat CTCL is bexarotene, a topical gel that is a synthetic retinoid analog. Bexarotene has been shown to be effective in clinical trials for stage IA or IB CTCL, and has fewer side effects than topical nitrogen mustard or electron beam radiotherapy. Another team of researchers at the University of Pennsylvania reported in 2003 that bexarotene combined with psoralen and UVA therapy is also effective in treating patients with advanced CTCL.

A treatment for advanced CTCL that is still considered experimental as of 2014 is alemtuzumab, a monoclonal antibody. A Swedish study of 22 patients with advanced CTCL and Sézary syndrome found that alemtuzumab relieved symptoms in 55% of patients, with 32% in complete remission and 23% in partial remission.

Alternatives

Itching of the skin is one of the most troublesome symptoms of CTCL. One alternative treatment for itchiness is the application of a brewed solution of chickweed that is applied to the skin using cloth compresses. Another suggested topical application is a mixture of **vitamin E**, vitamin A, unflavored yogurt, honey, and zinc oxide. Evening primrose oil applied topically is also claimed to reduce itch and promote healing.

Prognosis

The prognosis for CTCL is dependent on the stage of the disease. Prognosis is very good if the disease has only progressed to Stage IA, with a mean survival of 20 or more years. At this point, the disease is a very low mortality risk to the patient, with most deaths occurring to persons in this group unrelated to CTCL. For patients diagnosed at stages IB and IIA, the median survival is about 12 years. The disease in both of these stages involves intermediate risk to the patient. Patients in stage III and IVA have a mean life expectancy of about five years. At these later stages, the disease is high risk, with most deaths occurring by infection due to the depleted immune system of the later-stage patient. Once a patient has reached stage IVB, the mean life expectancy is one year.

Prevention

Studies have been unable to link CTCL to any environmental or genetic factors, so prevention at this time is not possible.

Cutis laxa

Definition

Cutis laxa (Latin for loose or lax skin) is a connective tissue disorder in which the skin lacks elasticity and hangs in loose folds.

Description

Cutis laxa is extremely rare; less than a few hundred cases worldwide have been described.

The several forms of cutis laxa are divided into primary cutis laxa, which is present from birth and is hereditary, secondary cutis laxa, which arises later in life and may be hereditary, and acquired cutis laxa, which arises later in life and is not hereditary. Loose skin, the primary and most obvious symptom of these diseases, is caused by underlying defects in connective tissue structure, which also cause more serious internal problems in vocal cords, bones, cartilage, blood vessels, bladder, kidney, digestive system, and lungs. The loose skin is particularly obvious on the face, and children with the disorder look sad or mournful.

There are four genetic forms of the disease: sex-linked, autosomal dominant, and two types of autosomal recessive inheritance. The recessive forms are the most common and are usually more severe than the other forms.

Causes and Symptoms

Sex-linked cutis laxa is caused by a defective gene on the X chromosome. In addition to loose skin, its symptoms are mild intellectual disabilities (ID), loose joints, bone abnormalities (like hooked nose, pigeon breast, and funnel breast), frequent loose stools, urinary tract blockages, and deficiencies in lysyl oxidase, an enzyme required for the formation of properly functioning connective tissue. (But the defective gene does not code for lysyl oxidase.)

Autosomal dominant cutis laxa is caused by a defective gene carried on an autosomal (not sex-linked) chromosome. Its symptoms are loose, hanging skin, missing elastic fibers, premature **aging**, and pulmonary **emphysema**. Only a few families are known with cutis laxa inherited as a dominant trait.

Autosomal recessive cutis laxa type 1 is caused by a defective gene on chromosome 5. Symptoms include emphysema; diverticula in the esophagus, duodenum, and bladder; lax and dislocated joints; tortuous arteries; hernias; lysyl oxidase deficiencies; and retarded growth.

Autosomal recessive cutis laxa type 2 is also inherited as a recessive trait. In addition to the loose skin, this form of the disease is characterized by bone abnormalities, the delayed joining of the cranial (skull) bones, hip dislocation, curvature of the spine, flat feet, and excessive **tooth decay**.

Acquired cutis laxa tends to follow (and may be caused by) severe illness characterized by **fever**, inflammation, and a severe skin rash (**erythema multiforme**); an injury to the nerves that control blood

WWW.BOOKBAZ.IR

KEY TERMS

Autosomal—Refers to the 22 pairs (in humans) of chromosomes not involved with sex determination.

Connective tissue—Tissue that supports and binds other tissue; much of it occurs outside of cells (extracellular) and consists of fibrous webs of the polymers, elastin and collagen. Cutis laxa is associated with defects in these fibers.

Diverticula—Pouches in the walls of organs.

Dominant trait—A genetic trait where one copy of the gene is sufficient to yield an outward display of the trait; dominant genes mask the presence of recessive genes; dominant traits can be inherited from only one parent.

Duodenum—The uppermost part of the small intestine, about 10 in (25 cm) long.

Esophagus—The tube connecting the throat to the stomach, about 10 in (25 cm) long.

Funnel breast (also known as pectus excavatum)—A condition where there is a hollow depression in the lower part of the chest.

Gene—A portion of a DNA molecule that either codes for a protein or RNA molecule or has a regulatory function.

Lysyl oxidase—An enzyme required for the crosslinking of elastin and collagen molecules to form properly functioning connective tissue; present in relatively low levels in at least some forms of cutis laxa.

Pigeon breast (also known as pectus carinatum)—A chest shape with a central projection resembling the keel of a boat.

Recessive trait—An inherited trait that is outwardly obvious only when two copies of the gene for that trait are present; an individual displaying a recessive trait must have inherited one copy of the defective gene from each parent.

Sex-linked—Refers to genes or traits carried on one of the sex chromosomes, usually the X.

Tortuous arteries—Arteries with many bends and twists.

X chromosome—One of the two types of sex chromosomes; females have two X chromosomes, while males have one X chromosome and one Y chromosome.

vessel dilation and contraction; or an autoimmune condition.

Diagnosis

The signs of cutis laxa are very obvious, and it is usually easy to diagnose by examining the skin. The determination of which form of cutis laxa is present is aided by information about the associated symptoms and by family histories.

Treatment

There is no effective cure for any of these disorders. Complications are treated by appropriate specialists, for example, cardiologists, gastroenterologists, rheumatologists, and dermatologists. **Plastic surgery** can be helpful for cosmetic purposes, but the skin may become loose again.

Prognosis

The prognosis for cutis laxa varies with the form of the disorder. The effects may be relatively mild with individuals living a fairly normal, full life, or the disease may be fatal.

Prevention

The inherited forms of cutis laxa are genetically determined and are not currently preventable. **Genetic counseling** can be helpful for anyone with a family history of cutis laxa. The cause of acquired cutis laxa is not known, so no preventive measures can be taken.

CVS *see* **Chorionic villus sampling; Cyclic vomiting syndrome**

Cyanosis

Definition

Cyanosis is a physical sign causing bluish discoloration of the skin and mucous membranes. Cyanosis is caused by a lack of oxygen in the blood. Cyanosis is associated with cold temperatures, **heart failure**, lung diseases, and smothering. It is seen in infants at birth as a result of heart defects, **respiratory distress syndrome**, or lung and breathing problems.

Description

Blood contains a red pigment (hemoglobin) in its red blood cells. Hemoglobin picks up oxygen from the lungs, then circulates it through arteries and releases it to cells through tiny capillaries. After giving up its oxygen, blood circulates back to the lungs through capillaries and veins. Hemoglobin, as well as blood, is bright red when it contains oxygen, but appears dark or "bluish" after it gives up oxygen.

The blue discoloration of cyanosis is seen most readily in the beds of the fingernails and toenails, and on the lips and tongue. It often appears transiently as a result of slowed blood flow through the skin due to the cold. As such, it is not a serious symptom. However, in other cases cyanosis is a serious symptom of underlying disease.

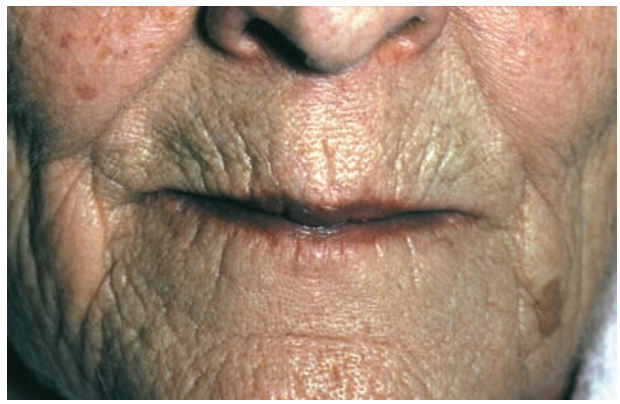
Causes and symptoms

The blue color of the skin and mucous membranes is caused by a lack of oxygen in the blood. Low blood oxygen may be caused by poor blood circulation, or heart or breathing problems. It can also be caused by being in a low-oxygen environment or by **carbon monoxide poisoning**. More rarely, cyanosis can be present at birth as a sign of **congenital heart disease**, in which some of the blood is not pumped to the lungs where oxygen would make the blood a bright red color. Instead, the blood goes to the rest of the body and remains unoxygenated. Cyanosis also may be caused by **poisoning** from chemicals, drugs, or contaminated food and water.

Other signs of low blood oxygen may accompany cyanosis, including feeling lightheaded or **fainting**.

Treatment

Treatment of the underlying disease can restore proper color to the skin.



This elderly woman's lips turned purple due to central cyanosis, a condition most commonly due to slow blood circulation, leading to a bluish skin coloration. *(Photo Researchers, Inc.)*

KEY TERMS

Hemoglobin—A colored substance (pigment) in the blood that carries oxygen to tissues and gives blood its red color.

Respiratory distress syndrome—Also known as hyaline membrane disease, this is a condition of premature infants in which the lungs are imperfectly expanded due to a lack of a substance on the lungs that reduces tension.

Prognosis

If the underlying condition (such as heart or lung disease) can be properly treated, the skin will return to its normal shade.

Cyclic vomiting syndrome

Definition

Cyclic **vomiting** syndrome (CVS) is a rare idiopathic disorder characterized by recurring periods of vomiting in an otherwise normal child or adult. It was

WWW.BOOKBAZ.IR

first described in 1882 by an English physician, Samuel Jones Gee. CVS is sometimes called abdominal migraine because it may be caused by some of the same mechanisms in the central nervous system that cause migraine headaches.

Description

Children in the pre–school or early school years are most susceptible to CVS, although the disorder can appear at any time from infancy to adulthood. One doctor reports that 43 of the 233 patients with CVS that he has treated were adults when their symptoms began. The average age of patients at onset is 5.2 years, but CVS has been diagnosed in patients as old as 73. This disorder was identified over a century ago, but its cause is still unknown. Episodes can be triggered by emotional **stress** or infections (particularly **sinusitis**), can last hours or days, and can return at any time. Abdominal **pain** is a frequent feature.

CVS appears to affect all races equally. The female:male ratio has been reported as 11:9.

Causes and symptoms

The cause of CVS is still unknown. Similarities to migraine suggest a common cause, but as yet no firm evidence has surfaced. It is known, however, that 82% of patients with CVS have a family history of migraine compared to 14% of control subjects. Patients can usually identify some factor that precedes an attack. Vomiting can be protracted and lead to such complications as **dehydration**; chemical imbalances; and tearing, burning, and bleeding of the esophagus (swallowing tube). Between attacks, there is no sign of any illness.

CVS has four distinct stages or phases:

- Prodrome. A prodrome is a warning symptom (or group of symptoms) that appears just before an acute attack of an illness. Patients with CVS often feel pain in the abdomen a few minutes or hours before the vomiting starts. Adults with CVS often have anxiety or panic attacks as a prodrome.
- Episode phase. During this phase, the patient is actively nauseated and vomiting. He or she may also feel drowsy or exhausted.
- Recovery phase.
- Symptom–free interval.

Diagnosis

The most important and difficult aspect of CVS is to be sure there is not an acute and life–threatening event in progress. So many different diseases can cause vomiting—from bowel obstruction to epilepsy—that an accurate and timely diagnosis is critical. Because there is no way to confirm a diagnosis of CVS, the physician must instead disprove every other diagnosis. This process, which is known as a diagnosis of exclusion, can be tedious, expensive, exhausting, and involving almost every system in the body. The first episode may be diagnosed as a stomach flu when nothing more serious turns up. Only after several episodes and several fruitless searches for a cause will a physician normally consider a diagnosis of CVS.

A careful history–taking is critical to making the correct diagnosis of CVS. A family history of migraine, particularly on the mother's side of the family, should alert the doctor to the possibility that the patient may have CVS.

In some cases, the doctor may refer the patient to a psychiatrist for evaluation in order to rule out **anxiety disorders** or an eating disorder.

KEY TERMS

Abdominal migraine—Another term that is sometimes used for CVS.

Idiopathic—Of unknown cause or spontaneous origin. CVS is sometimes called an idiopathic disorder because its cause(s) are still not known.

Prodrome—A symptom or group of symptoms that appears shortly before an acute attack of illness. The term comes from a Greek word that means "running ahead of."

Treatment

Several different medications have given good results in small trials. The **antimigraine drugs** amitriptyline and cyproheptadine performed well for one study group. Propranolol is sometimes effective, and erythromycin helped several patients in one study, not because it is an antibiotic but because it irritates the stomach and encourages it to move its contents forward instead of in reverse.

Another medication that has been reported to be successful in treating children with CVS is dexmedetomidine (Precedex), a drug originally developed to sedate patients on respirators in intensive care settings. Researchers found that dexmedetomidine relieved the **anxiety** as well as the nausea associated with CVS.

Antiemetic medication such as ondansetron (Zofran), antianxiety medication such as lorazepam

(Ativan) and medication for stomach acid irritation such as ranitidine (Zantac) may be helpful during the prodrome phase.

Acupuncture treatments have also been found to be helpful to some children with CVS.

Patients are urged to drink plenty of water and electrolyte fluids to stay healthy during the recovery phase, moving slowly to solid food as tolerated.

Prognosis

The disease may go on for many years without a change in pattern. If the acute complications of prolonged vomiting can be successfully prevented or managed, most patients can lead normal lives between episodes. Medications may ease the symptoms during attacks.

Cyclospora infection *see* **Cyclosporiasis**

Cyclosporiasis

Definition

Cyclosporiasis refers to infection by the spore-forming protozoan known as *Cyclospora*. Protozoa are a group of parasites that infect the human intestine. Parasites are organisms that live in another body, called the host, and get food and liquids from that host. This parasite is a member of the group of protozoa known as coccidia, to which *Cryptosporidia* also

WWW.BOOKBAZ.IR

KEY TERMS

Anti-motility medications—Medications such as loperamide (sold as Imodium), dephenoxylate (sold as Lomotil), or medications containing codeine or narcotics that decrease the ability of the intestine to contract. This can worsen the condition of a patient with dysentery or colitis.

Cyst—A protective sac that includes either fluid or the cell of an organism. The cyst enables many organisms to survive in the environment for long periods of time without need for food or water.

Immunocompromised—A change or alteration of the immune system that normally serves to fight off infections other illnesses. This can involve changes in antibodies that the body produces (hygogammaglobulinemia), or a defect in the cells that partake in the immune response. Diseases such as AIDS and cancer exhibit changes in the body's natural immunity.

Oral Rehydration Solution (ORS)—A liquid preparation developed by the World Health Organization that can decrease fluid loss in persons with diarrhea. Originally developed to be prepared with materials available in the home, commercial preparations have recently come into use.

Parasite—An organism that lives on or in another and takes nourishment (food and fluids) from that organism.

Protozoa—Group of extremely small single cell (unicellular) or acellular organisms that are found in moist soil or water. They tend to exist as parasites, living off other life forms.

Spore—A resistant form of certain species of bacteria, protozoa, and other organisms.

belongs. This group of parasites infects the human intestine, and causes chronic recurrent infections in those with altered immunity or **AIDS**. Even in people with normal immune function, *Cyclopsora* can cause prolonged bouts of **diarrhea** and other gastrointestinal symptoms.

Description

Until recently, *Cyclospora* was considered to be a form of algae. The parasite causes a common form of waterborne infectious diarrhea throughout the world. Just how the parasite gets into water sources is not yet clear. It is known that ingestion of small cysts in contaminated water leads to disease.

Causes and symptoms

Symptoms begin after an incubation period of about a day or so following ingestion of cysts. A brief period of flu-like illness characterized by weakness and low-grade **fever** is followed by watery diarrhea, nausea, loss of appetite, and muscle aches. In some patients, symptoms may wax and wane for weeks, and there are those in whom nausea and burping may predominate. It is also believed that infection can occur without any symptoms at all.

In patients with abnormal immunity (immunocompromised patients), such as those with AIDS and cancer, prolonged diarrhea and severe weight loss often become a major problem. The bile ducts are also susceptible to infection in AIDS patients.

Diagnosis

The disease should be suspected in anyone with a history of prolonged or recurrent diarrhea. The parasite is identified either by staining stool specimens or by applying certain fluorescent ultraviolet techniques to find the characteristic cysts. Biopsy of an infected organ such as the intestine through an endoscope is another way to make the diagnosis.

Treatment

The first aim of treatment as with any severe diarrheal illness is to avoid **dehydration** and **malnutrition**. Oral Rehydration Solution (ORS) or intravenous fluids are sometimes needed. Medications used to treat diarrhea by decreasing intestinal motility, such as loperamide or diphenoxylate are also useful, but should only be used with the advice of a physician.

The use of the medication, trimethoprim-sulfamethoxazole (Bactrim) for one week can be successful in treating intestinal infections and prevents relapse in those with a normal immune system. The same medicine can be prescribed to treat infections of both the intestine or bile ducts in immunocompromised individuals, but maintenance or continuous treatment is often needed.

Prognosis

The outlook is quite good for individuals in whom a diagnosis is made. Even without treatment, symptoms usually do not last much more than a month except in cases with altered immunity. Fortunately, treatment is usually successful even in those patients.

Prevention

Aside from a waterborne source as the origin of infection, little else is known about how the parasite is transmitted. Therefore, little can be done regarding prevention, except to maintain proper hand washing techniques and hygiene.

Cyclosporine *see* **Immunosuppressant drugs**

Cystectomy

Definition

Cystectomy is a surgical procedure to remove the bladder.

Purpose

Cystectomy is performed to treat cancer of the bladder. Radiation and **chemotherapy** are also used to treat **bladder cancer**. Surgery is used to remove cancer when it is in the muscle of the bladder.

Precautions

Cystectomy is an aggressive treatment that may not be appropriate for patients with superficial tumors that respond to more conservative treatment.

Description

Cystectomy is a major surgical operation. The patient is placed under general **anesthesia**. An incision is made across the lower abdomen. The ureters are located, tied and cut. The ureters connect the kidneys to the bladder. Cutting them frees the bladder for removal. The bladder and associated organs are removed. In men the prostate is removed with the bladder. In women, the uterus, fallopian tubes, ovaries, and part of the vagina are removed with the bladder. The bladder collects urine from the kidneys for excretion at a later time. Since the bladder is removed, a new method must be created to remove the urine. A small piece of the small intestine is removed, cleaned, and tied at one end to form a tube. The other end is used to form a stoma, an opening through the abdominal wall to the outside. The ureters are then connected to the tube. Urine produced by the kidneys now flows down the ureters, into the tube, and through the stoma. The patient wears a bag to collect the urine.

Preparation

The medical team will discuss the procedure and tell the patient where the stoma will appear and what it will look like. The patient receives instruction on caring for a stoma and bag. Counseling may be initiated. A period of **fasting** and an enema may be required.

Aftercare

After the operation, the patient is given fluid-based **nutrition** until the intestines being to function normally again. **Antibiotics** are given to prevent infection of the incision sites. The nature of the organs removed mean that there will be major lifestyle changes for the person undergoing the operation. Men will become impotent because nerves controlling penile erection are cut during removal of the bladder. In women, **infertility** is a consequence because the ovaries and uterus are removed. However, most women who undergo cystectomy are postmenopausal and past their childbearing years.

Both men and women are fitted with an external bag that connects to the stoma and collects the urine. The bag is generally worn around the waist under the clothing. It takes a period of adjustment to get used to wearing the bag. Because there is no bladder, urine is excreted as it is produced, essentially continuously. The stoma must be treated properly to ensure that it does not become infected or blocked. Patients must be trained to care for their stoma. Often there is a period of psychological adjustment to the major change in life style created by the stoma and bag. Patients should be prepared for this by discussion with their physician.

WWW.BOOKBAZ.IR

KEY TERMS

Ureters—Tubes that connect the kidneys to the bladder. Urine produced by the kidneys passes through the ureters to the bladder.

Risks

As with any major surgery, there is a risk of infection; in this case infection of the intestine is especially dangerous as it can lead to **peritonitis** (inflammation of the membrane lining the abdomen).

Results

Normal results

The bladder is successfully removed and a stoma created. Intestinal function returns to normal and the patient learns proper care of the stoma and bag. He or she adjusts to lifestyle changes and returns to a normal routine of work and recreation, some sports excluded.

Abnormal results

The patient develops an infection at the incision site. The patient does not make a successful psychological adjustment to the long term consequences of **impotence** and urinary diversion. In some women, the vagina is constricted, which may require a secondary procedure.

Cystic fibrosis

Definition

Cystic fibrosis is an inherited disease that affects the lungs, digestive system, sweat glands, and male fertility. Its name derives from the fibrous scar tissue that develops in the pancreas, one of the principal organs affected by the disease.

Description

Cystic fibrosis (CF) is a disease of the mucus glands that affects many body systems. CF affects the body's ability to move salt and water in and out of cells, resulting in progressive damage to the respiratory system and chronic digestive system problems. It causes the lungs and pancreas to secrete thick mucus that blocks passageways and prevents proper function.

Many symptoms of CF can be treated with drugs or **nutritional supplements**. Close attention to and prompt treatment of respiratory and digestive complications have dramatically increased the expected life span of a person with CF. In the last quarter of the twentieth century, most children with CF died by age two years. In the 2010s, about half of all people with CF live past age 31. That median age is expected to increase as new treatments are developed, and it is estimated that a person born in 1998 with CF has a median expected life span of 40 years.

Risk factors

Cystic fibrosis is an inherited disease. Children born to individuals who are Caucasian and of Northern European descent are more likely to be born with CF than children of other racial and ethnic groups. Children of parents who are of African or Asian descent are less likely to have CF. Because CF requires both copies of the child's DNA to have the relevant mutation, children with parents who are both of Northern European descent are at higher risk than children who have just one parent of that descent.

Demographics

According to the Cystic Fibrosis Foundation, in 2014, about 30,000 people in the United States and 70,000 worldwide had cystic fibrosis. It was one of the most common inherited diseases among Caucasians. About 1,000 new cases were diagnosed each year. CF occurred in about 1 in 3,700 births overall in the United States, and in about 1 in 2,500 births to parents of Northern European descent. About 12 million Americans were likely to be carriers of a faulty CF gene, and many did not know that they were CF carriers. About half of all individuals with CF in the United States were as of 2014 over 18 years of age.

Cystic fibrosis affects males and females equally and people from all racial and ethnic groups. However, the disease is most common among Caucasians of Northern European descent. It also occurs among Latinos and Native Americans, especially the Pueblo and Zuni. Cystic fibrosis is much less common among African Americans and Asian Americans.

DOROTHY ANDERSEN (1901–1963)

(The Library of Congress.)

Dorothy Andersen was born on May 15, 1901, in Asheville, North Carolina. She was the only child of Hans Peter Andersen and the former Mary Louise Mason. Orphaned as a young adult, Andersen put herself through Saint Johnsbury Academy and Mount Holyoke College before enrolling in the Johns Hopkins School of Medicine, from which she received her M.D. in 1926.

Andersen turned to medical research as a pathologist at Babies Hospital of the Columbia-Presbyterian Medical Center in New York City, where she worked for more than 20 years, eventually becoming chief of pathology in 1952. Andersen is probably best known for her discovery of cystic fibrosis in 1935. That discovery came about during the postmortem examination of a child who had supposedly died of celiac disease, a nutritional disorder. She searched for similar cases in the autopsy files and in medical literature, eventually realizing that she had found a disease that had never been described and to which she gave the name cystic fibrosis.

Causes and symptoms

Cystic fibrosis is a genetic disease, meaning it is caused by a defect in the person's genes. Genes, found in the nucleus of all the body's cells, control cell function by serving as the blueprint for the production of proteins. Proteins carry out a wide variety of functions within cells. The gene that, when defective, causes CF is called the CFTR gene, which stands for cystic fibrosis transmembrane conductance regulator. A simple change in this gene leads to all the consequences of CF. There are over 1,000 known defects in the CFTR gene that can cause CF. However, 70% of all people with an abnormal CFTR gene have the same defect, known as delta–F508.

Genes can be thought of as long strings of chemical words, each made of chemical letters, called nucleotides. Just as a sentence can be changed by rearranging its letters, genes can be mutated, or changed, by changes in the sequence of their nucleotide letters. The gene changes in CF are called point mutations, meaning that the gene is mutated only at one small spot along its length. In other words, the delta–F508 mutation is a loss of one "letter" out of thousands within the CFTR gene. As a result, the CFTR protein made from its blueprint is made incorrectly and cannot perform its function properly.

The CFTR protein helps to produce mucus. Mucus is a complex mixture of salts, water, sugars, and proteins that cleanses, lubricates, and protects many passageways in the body, including those in the lungs and pancreas. The role of the CFTR protein is to allow chloride ions to exit the mucus-producing cells. When the chloride ions leave these cells, water follows, thinning the mucus. In this way, the CFTR protein helps to keep mucus from becoming thick and sluggish, thus allowing the mucus to be moved steadily along the passageways to aid in cleansing.

In CF, the CFTR protein does not allow chloride ions out of the mucus-producing cells. With less chloride leaving, less water leaves, and the mucus becomes thick and sticky. It can no longer move freely through the passageways, so they become clogged. In the pancreas, clogged passageways prevent secretion of digestive enzymes into the intestine, causing serious impairment of digestion—especially of fat. This may lead to **malnutrition**. Mucus in the lungs may plug the airways, preventing good air exchange and, ultimately, leading to **emphysema**. The mucus is also a rich source of nutrients for bacteria, leading to frequent infections.

To understand the inheritance pattern of CF, it is important to realize that genes actually have two functions. First, they serve as the blueprint for the production of proteins. Second, they are the material of inheritance: Parents pass on characteristics to their

WWW.BOOKBAZ.IR

children by combining the genes in egg and sperm to make a new individual.

All individuals have two copies of each gene, including the CFTR gene, in each of their body cells. During sperm and egg production, however, these two copies separate, so that each sperm or egg contains only one copy of each gene. When sperm and egg unite, the newly created cell once again has two copies of each gene. This process keeps the number of genes constant from generation to generation.

The two gene copies may be the same, or they may be slightly different. For the CFTR gene, for instance, a person may have two normal copies or one normal and one mutated copy or two mutated copies. A person with two mutated copies will develop cystic fibrosis. A person with one mutated copy is said to be a carrier. Carrier will not have symptoms of CF but can pass on the mutated CFTR gene to their children.

When two carriers have children, they have a one-in-four chance of having a child with CF each time they conceive. They have a two-in-four chance of having a child who is a carrier and a one-in-four chance of having a child with two normal CFTR genes.

Approximately one in every 25 Americans of northern European descent is a carrier of the mutated CF gene, whereas only one in 17,000 African Americans and one in 30,000 Asian Americans are carriers. Since carriers are symptom-free, very few people know whether they are carriers, unless there is a family history of the disease. Two white Americans with no family history of CF have a one in 2,500 chance of having a child with CF.

It may seem puzzling that a mutated gene with such harmful consequences would remain so common; one might guess that the high mortality associated with CF would quickly lead to loss of the mutated gene from the population. Some researchers believe the reason for the persistence of the CF gene is that carriers, those with only one copy of the gene, are protected from the full effects of **cholera**, a microorganism that infects the intestine, causing intense **diarrhea** and, if left untreated, eventual death by **dehydration**. It is believed that having one copy of the CF gene is enough to prevent the full effects of cholera infection whereas not enough to cause the symptoms of CF. This so-called heterozygote advantage is seen in some other genetic disorders, including sickle-cell disease.

The most severe effects of cystic fibrosis are seen in two body systems: the gastrointestinal (digestive) system and the respiratory tract, from the nose to the lungs. CF also affects the sweat glands and male fertility. Symptoms develop gradually, with gastrointestinal symptoms often the first to appear.

Gastrointestinal system

About 10% to 15% of babies who inherit CF have meconium **ileus** at birth. Meconium is the first dark stool that a baby passes after birth. Ileus is an obstruction of the digestive tract. The meconium of a newborn with meconium ileus is thickened and sticky, due to the presence of thickened mucus from the intestinal glands. Meconium ileus causes abdominal swelling and **vomiting** and often requires surgery immediately after birth. Presence of meconium ileus is considered highly indicative of CF. Borderline cases may be misdiagnosed, however, and attributed instead to a milk allergy.

Other abdominal symptoms are caused by the inability of the pancreas to supply digestive enzymes to the intestine. During normal digestion, as food passes from the stomach into the small intestine, it is mixed with pancreatic secretions, which help to break down the nutrients for absorption. While the intestines themselves also provide some digestive enzymes, the pancreas is the major source of enzymes for the digestion of all types of foods, especially fats and proteins.

In CF, thick mucus blocks the pancreatic duct, which eventually is closed off completely by scar tissue, leading to a condition known as pancreatic insufficiency. Without pancreatic enzymes, large amounts of undigested food pass into the large intestine. Bacterial action on this rich food source can cause gas and abdominal swelling. The large amount of fat remaining in the feces makes it bulky, oily, and foul-smelling.

Because nutrients are only poorly digested and absorbed, individuals with CF are often ravenously hungry, underweight, and shorter than expected for their age. When CF is not treated for a longer period, children with CF may develop symptoms of malnutrition, including anemia, bloating, and, paradoxically, appetite loss.

Diabetes becomes increasingly likely as individuals with CF age. Scarring of the pancreas slowly destroys those pancreatic cells that produce insulin, producing type I, or insulin-dependent, diabetes.

Gallstones affect approximately 10% of adults with CF. Liver problems are less common but can be caused by the build-up of fat within the liver. Complications of liver enlargement may include internal hemorrhaging, abdominal fluid (**ascites**), spleen enlargement, and liver failure.

Other gastrointestinal symptoms can include a prolapsed rectum, in which case part of the rectal lining protrudes through the anus; intestinal obstruction; and rarely, **intussusception**, in which part of the intestinal tube slips over an adjoining part, cutting off blood supply.

Somewhat fewer than 10% of people with CF have no gastrointestinal symptoms. Most of these people do not have the delta–F508 mutation; these individuals have a different one, which presumably allows at least some of their CFTR proteins to function normally in the pancreas.

Respiratory tract

The respiratory tract includes the nose, throat, trachea (or windpipe), bronchi (which branch off from the trachea within each lung), smaller bronchioles, and blind sacs called alveoli, in which gas exchange takes place between air and blood.

Swelling of the sinuses within the nose is common in people with CF. This symptom usually shows up on x ray and may aid the diagnosis of CF. However, this swelling, called pansinusitis, rarely causes problems and does not usually require treatment.

Nasal polyps, or growths, affect about one in five people with CF. These growths are not cancerous and do not require removal unless they become annoying. While nasal polyps appear in older people without CF, especially those with **allergies**, they are rare in children without CF.

The lungs are the site of the most life-threatening effects of CF. The production of a thick, sticky mucus increases the likelihood of infection, decreases the ability to protect against infection, causes inflammation and swelling, decreases the functional capacity of the lungs, and may lead to emphysema. People with CF live with chronic populations of bacteria in their lungs, and lung infection is the major cause of death for these individuals.

The bronchioles and bronchi normally produce thin, clear mucus that traps foreign particles, including bacteria and viruses. Tiny hair-like projections called cilia on the surface of these passageways slowly sweep the mucus along, out of the lungs and up the trachea to the back of the throat, where it may be swallowed or coughed up. This so-called mucociliary escalator is one of the principal defenses against lung infection.

The thickened mucus typical of CF prevents easy movement out of the lungs and increases the irritation and inflammation of lung tissue. This inflammation swells the passageways, partially closing them, further hampering the movement of mucus. A person with CF is likely to **cough** more frequently and more vigorously as the lungs attempt to clean themselves out.

At the same time, infection becomes more likely since the mucus is a rich source of nutrients. **Bronchitis**, **bronchiolitis**, and **pneumonia** are frequent in individuals with CF. The most common infecting organisms are the bacteria *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*. A small percentage of people with CF have infections caused by *Burkholderia cepacia*, a bacterium that as of 2014 was resistant to most **antibiotics**. The fungus *Aspergillus fumigatus* may infect older children and adults.

The body's response to infection is to increase mucus production; white blood cells fighting infection thicken the mucus even further as they break down and release their cell contents. These white blood cells also provoke more inflammation, continuing the downward spiral that marks untreated CF.

Accumulating mucus can plug the smaller passageways in the lungs, decreasing functional lung volume. Getting enough air can become difficult; tiredness, **shortness of breath**, and intolerance of **exercise** become more common. Because air passes obstructions more easily during inhalation than during exhalation, over time, air becomes trapped in the smallest chambers of the lungs, the alveoli. As millions of alveoli gradually expand, the chest takes on the enlarged, barrel-shaped appearance typical of emphysema.

For unknown reasons, recurrent respiratory infections lead to digital clubbing, in which the last joint of the fingers and toes becomes slightly enlarged.

Sweat glands

The CFTR protein helps to regulate the amount of salt in sweat. People with CF have sweat that is much saltier than normal, and measuring the saltiness of a person's sweat is the most important diagnostic test for CF. Parents may notice that their infant tastes salty when they kiss them. Excess salt loss is not usually a problem except during prolonged exercise or heat. While most older children and adults with CF compensate for this extra salt loss by eating more salty foods, infants and young children are in danger of suffering its effects (e.g., heat prostration), especially during summer. Heat prostration is marked by lethargy, weakness, and loss of appetite, and should be treated as an emergency condition.

Fertility

Some 98% of men with CF are sterile, due to complete obstruction or absence of the vas deferens,

WWW.BOOKBAZ.IR

the tube carrying sperm out of the testes. While boys and men with CF form normal sperm and have normal levels of sex hormones, sperm are unable to leave the testes, and fertilization is not possible. Most women with CF are fertile, though they often have more trouble getting pregnant than women without CF. In both boys and girls with CF, **puberty** is often delayed, most likely due to the effects of poor **nutrition** or chronic lung infection. Women with good lung health usually have no problems with **pregnancy**, whereas those with ongoing lung infection often do poorly.

Diagnosis

In the United States hospitals routinely screen newborns for CF. Previously, the decision to test a child for cystic fibrosis was often triggered by concerns about recurring gastrointestinal or respiratory symptoms, salty sweat, or a meconium ileus will be tested before the newborn leaves the hospital. The habit of testing only when prompted by concerns perhaps led to missed cases of CF, causing delayed treatment.

Sweat test

The **sweat test** is both the easiest and most accurate test for CF. In this test, a small amount of the drug pilocarpine is placed on the skin. A very small electrical current is then applied to the area, which drives the pilocarpine into the skin. The drug stimulates sweating in the treated area. The sweat is absorbed by a piece of filter paper and is then analyzed for its salt content. Persons with CF have salt concentrations that are 1.5 to 2 times greater than normal. The test can be done on persons of any age, including newborns, and its results can be determined within an hour. Virtually every person who has CF tests positively on it, and virtually everyone who does not will test negatively.

Genetic testing

The discovery of the CFTR gene in 1989 allowed the development of a genetic test for CF. Genes from a small blood or tissue sample are analyzed for specific mutations; presence of two copies of the mutated gene confirms the diagnosis of CF in all but a very few cases. However, since there are so many different possible mutations, and since testing for all of them would be too expensive and time-consuming, a negative gene test cannot rule out the possibility of CF.

Couples who plan to have a family may decide to have themselves tested if either member of the pair has a family history of CF. Prenatal **genetic testing** is possible through **amniocentesis**. Many couples who already have one child with CF decide to undergo prenatal screening in subsequent pregnancies. Siblings in these families are also usually tested, both to determine if they will develop CF and to determine if they are carriers, information that can aid them in their own family planning. If siblings have no symptoms, determining their carrier status is often delayed until the teen years or later, when they are closer to needing the information to make reproductive decisions.

Newborn screening

Newborn screening for CF is often done using a test known as the IRT test. This blood test measures the level of immunoreactive trypsinogen, which is generally higher in babies with CF than those without it. This test gives many false positive results immediately after birth, and so requires a second test several weeks later. A second positive result is usually followed by a sweat test.

Treatment

There is no cure for cystic fibrosis. Treatment advanced considerably in the late twentieth century, increasing both the life span and the quality of life for most people affected by CF. Early diagnosis is important to prevent malnutrition and infection from weakening individuals with CF. With proper management, many people with CF engage in the full range of school and sports activities.

People with CF usually require high-calorie **diets** and vitamin supplements. Height, weight, and growth of individuals with CF are monitored regularly. Most people with CF need to take pancreatic enzymes to supplement or replace the inadequate secretions of the pancreas. Tablets containing pancreatic enzymes are taken with every meal; depending on the size of the tablet and the meal, as many as 20 tablets may be needed. Because of incomplete absorption even with pancreatic enzymes, individuals with CF need to take in about 30% more food than individuals without CF. Low-fat diets are *not* recommended except in special circumstances, since fat is a source of both essential fatty acids and abundant calories.

Some people with CF cannot absorb enough nutrients from the foods they eat, even with specialized diets and enzymes. For these people, tube feeding is an option. Nutrients can be introduced directly into the stomach through a tube inserted either through the nose (a **nasogastric tube**) or through the abdominal wall (a **gastrostomy** tube). A jejunostomy tube, inserted into the small intestine, is also an option. Tube feeding can provide nutrition at any time, including at night while the person is sleeping,

allowing constant intake of high-quality nutrients. The feeding tube may be removed during the day, allowing normal eating of meals during waking hours.

The key to maintaining respiratory health in individuals with CF is regular monitoring and early treatment. Lung function tests are done frequently to track changes in functional lung volume and respiratory effort. Sputum samples are analyzed to determine the types of bacteria present in the lungs. Chest x rays are usually taken at least once a year. Lung scans, using a radioactive gas, can show closed off areas not seen on the x ray. Circulation in the lungs may be monitored by injection of a radioactive substance into the bloodstream.

People with CF live with chronic bacterial colonization; that is, their lungs are constantly host to several species of bacteria. Good general health, especially good nutrition, can keep the immune system healthy, which decreases the frequency with which these colonies begin an infection or attack on the lung tissue. Exercise is another important way to maintain health, and people with CF are encouraged to maintain a program of regular exercise.

In addition, clearing mucus from the lungs helps to prevent infection, and mucus control is an important aspect of CF management. Bronchial drainage is used to allow gravity to aid the mucociliary escalator. For this technique, the person with CF lies on a tilted surface with head downward, alternately on the stomach, back, or side, depending on the section of lung to be drained. An assistant thumps the rib cage to help loosen the secretions. Regular thumping on the front and back of the chest can help loosen mucus, allowing easier expelling even in the absence of a tilted surface. A device called a flutter offers another way to loosen secretions. It consists of a stainless steel ball in a tube. When a person exhales through it, the ball vibrates, sending vibrations back through the air in the lungs. Some special breathing techniques may also help clear the lungs. In some cases, an endoscope may be used to suction mucus from the airway.

Supplemental oxygen may be needed as lung disease progresses. **Respiratory failure** may develop, requiring temporary use of a ventilator to perform the work of breathing.

Drugs

Drugs are administered to treat specific symptoms and also to prevent or slow symptoms. Drug regimens are highly individualized based on age, symptoms, and severity of the disease. Several drugs are available to prevent the airways from becoming clogged with mucus. **Bronchodilators** can help open up the airways; **steroids** reduce inflammation; and mucolytics loosen secretions. Acetylcysteine (Mucomyst) was used as a mucolytic for many years but subsequently was not prescribed frequently. DNase (Pulmozyme) was a newer product that gained popularity. DNase breaks down the DNA from dead white blood cells and bacteria found in thick mucus.

Some doctors choose to prescribe antibiotics only during infection, whereas others prefer long-term antibiotic treatment against *S. aureus*. The choice of antibiotic depends on the particular organism or organisms found. Azithromycin has been found to be beneficial for individuals with certain chronic bacterial infections. Some antibiotics, including TOBI (aerosolized tobramycin) and Cayston (aerosolized aztreonam lysine), are given as aerosols directly into the lungs. This delivery method has been found to be effective at decreasing hospitalization days and increasing lung function. As of 2014, other aerosolized antibiotics were in clinical trials. Antibiotic treatment may be prolonged and aggressive.

Long-term use of ibuprofen has been shown to help some people with CF, presumably by reducing inflammation in the lungs. A daily dose of 20–30 mg per kg is recommended for CF patients who are under the age of 15 as it has been shown to slow the progression of lung disease in some CF patients in this age range. Close medical supervision is necessary, however, since the effective dose is high and not everyone benefits. Ibuprofen at the required doses interferes with kidney function and, together with aminoglycoside antibiotics, may cause kidney failure.

In January 2012, the drug ivacaftor (Kalydeco) produced by Vertex Pharmaceuticals was approved by the United States Food and Drug Administration (FDA). The drug was approved for individuals with CF over the age of six. In clinical trials, it was found to improve lung function by about 10% versus placebos, which lasted through 48 weeks of treatment and testing. Individuals taking this drug also had to take fewer antibiotics due to problems with their sinuses or lungs, and children ages 6 to 11 gained about 6 more pounds when taking the drug than when taking a placebo.

Kalydeco works by increasing the rate at which chloride moves in and out of the cells of the lungs, improving the balance of salt and water and improving lung function. Unfortunately, the drug is only effective for individuals with one of nine identified genetic mutations and is not effective for many CF patients with two copies of the F508del mutation.

WWW.BOOKBAZ.IR

KEY TERMS

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Cystic fibrosis transmembrane conductance regulator (CFTR)—The protein responsible for regulating chloride movement across cells in some tissues. When a person has two defective copies of the CFTR gene, cystic fibrosis is the result.

Emphysema—A chronic lung disease that begins with breathlessness during exertion and progresses to shortness of breath at all times, caused by destructive changes in the lungs.

Mucociliary escalator—The coordinated action of tiny projections on the surfaces of cells lining the respiratory tract, which moves mucus up and out of the lungs.

Mucolytic—An agent that dissolves or destroys mucin, the chief component of mucus.

Pancreatic insufficiency—Reduction or absence of pancreatic secretions into the digestive system due to scarring and blockage of the pancreatic duct.

Additional treatments

Lung transplantation is another option for people with CF, although the number of people who receive a lung is much lower than those who want them. Transplantation is not a cure, however, and has been likened to trading one disease for another. Long-term **immunosuppression** is required, increasing the likelihood of other types of infection. About 50% of adults and more than 80% of children who receive lung transplants live longer than two years. Some patients with CF whose livers have been damaged by fibrosis also undergo liver transplants.

A number of experimental treatments were the subject of much research in 2014. Some evidence indicated that aminoglycoside antibiotics may help overcome the genetic defect in some CF mutations, allowing the protein to be made normally. While promising, these results would apply to only about 5% of those with CF.

Gene therapy was viewed as the most ambitious approach to curing CF. In this set of techniques, nondefective copies of the CFTR gene are delivered to affected cells, where they are taken up and used to create the CFTR protein. While elegant and simple in theory, gene therapy met with a large number of difficulties in trials, including immune resistance, very short duration of the introduced gene, and inadequately widespread delivery.

Alternatives

Treating the cause of CF, because of the genetic basis for the disease, is not possible. However, complementary treatment might include:

- mucolytics to help thin mucous
- supplementation of pancreatic enzymes to assist in digestion
- respiratory symptoms addressed to open lung passages
- hydrotherapy techniques to help ease the respiratory symptoms and help the body eliminate mucus
- immune enhancements to help prevent the development of secondary infections
- dietary enhancements and adjustments to treat digestive and nutritional problems

Prognosis

People with CF may lead relatively normal lives. The possible effect of pregnancy on the health of a woman with CF requires careful consideration before pregnancy begins. Prospective mothers need to consider issues of longevity and their children's status as carriers. Although most men with CF are functionally sterile, there are procedures for removing sperm from the testes that may offer more men the chance to become fathers.

Approximately half of people with CF live past the age of 30. Because of better and earlier treatment, a person born in 2014 with CF was expected, on average, to live to age 40.

Prevention

CF is a genetic disorder that cannot be prevented. Screening people with a family history of CF may detect the cystic fibrosis gene in 60–90% of carriers, depending on the test used.

Cystinuria

Definition

Cystinuria is an inborn error of amino acid transport that results in the defective absorption by the kidneys of the amino acid called cystine. The name means "cystine in the urine."

Description

Cystine is an amino acid. Amino acids are organic compounds needed by the body to make proteins and for many normal functions. When the kidneys do not absorb cystine, this compound builds up in the urine. When the amount of cystine in the urine exceeds its solubility (the greatest amount that can be dissolved), crystals form. As the amount of cystine continues to increase in the urine, the number of crystals also increases. When very large numbers of cystine crystals form, they clump together into what is called a stone.

Causes and symptoms

Cystinuria is a rare disease that occurs when people inherit an abnormal gene from their parents. This disease occurs in differing degrees of severity in people who have inherited either one or two abnormal genes. Humans have two copies of each gene. When both are abnormal, the condition is called homozygous for the disease. When one copy is normal and the other is abnormal, the condition is called heterozygous for the disease. Persons with one abnormal gene can have a milder form of cystinuria that rarely results in the formation of stones.

Severe cystinuria occurs when people are homozygous for the disease. For these individuals, the kidneys may excrete as much as 30 times the normal amount of cystine. Research has shown that this condition is caused by mutations on chromosome number two (humans have 23 pairs of chromosomes).

A person who has inherited cystinuria may have other abnormal bodily functions. In addition to excess levels of the amino acid cystine, high amounts of the amino acids lysine, arginine, and ornithine are found in the urine. This condition indicates that these amino acids are not being reabsorbed by the body.

When excess cystine crystals clump together to form a stone, the stone can block portions of the interior of the kidney or the tube (the ureter) that connects the kidney to the urinary bladder. These cystine stones can be painful, and depending upon where the stone becomes trapped, the **pain** can be felt in the lower back or the abdomen. **Nausea and**

WWW.BOOKBAZ.IR

KEY TERMS

Alkaline—A solution is considered alkaline if it contains fewer hydrogen atoms than pure water.

Amino acid—An organic compound made of an amino group (containing nitrogen and hydrogen) and a carbolic acid group. Amino acids are an essential part of protein molecules.

Nephroscope—An instrument made of a light source in a tube. The tube is inserted into the kidney through an incision in the back and used to locate kidney stones. The stones are broken up with high frequency sound waves and removed by suction through the scope.

Nitroprusside—A compound that is used in laboratory tests to identify large amounts of cystine in urine samples.

Uretoscope—A tube-shaped device inserted into the body through the urinary system that allows objects to be both seen and grasped for removal.

vomiting can also occur, and patients may sometimes feel the need to urinate often. Cystine stones can also cause blood in the urine. When the urinary tract is blocked by a stone, urinary tract infections or kidney failure may result.

Diagnosis

Small stones (called "silent") often do not cause any symptoms, although they can be detected by an x ray. Large stones are often painful and easily noticed by the patient. Blood in the urine can also mean that a stone has formed.

When the urine contains extremely high amounts of cystine, yellow-brown hexagonal crystals are visible when a sample is examined under the microscope. Urine samples can also be mixed with chemicals that change color when high levels of cystine are present. When the compound nitroprusside is added to urine that has been made alkaline by the addition of ammonia, the urine specimen turns red if it contains excess cystine.

Treatment

No treatment can decrease cystine excretion. The best treatment for cystinuria is to prevent stones from forming. Stones can be prevented by drinking enough liquid each day (about 5–7 qts) to produce at least 8 pts of urine, thus keeping the concentration of cystine in the urine low. Because a person does not drink throughout the night, less urine is produced, and the likelihood of stone formation increases. This risk can be minimized by drinking water or other liquids just before going to bed.

Drug treatments

In addition to drinking large amounts of fluids, it is helpful to make the urine more alkaline. Cystine dissolves more easily in alkaline urine. To increase urine alkalinity, a person may take **sodium** bicarbonate and acetazolamide. Penicillamine, a drug that increases the solubility of cystine, may be prescribed for patients who do not respond well to other therapies. This drug must be used with caution, however, because it can cause serious side effects or allergic reactions. For those unable to take penicillamine, another drug, alpha-mercaptopropionylglycine (Thiola), may be prescribed.

Surgical treatments

Most stones can be removed from the body by normal urination, helped by drinking large amounts of water. Large stones that cannot be passed this way must be removed by surgical procedures.

Large stones can be surgically removed by having a device called a uretoscope placed into the urethra, up through the bladder and into the ureter, where the trapped stone can be seen and removed. Another method involves using sound-wave energy aimed from outside the body to break the large stone into small pieces that can be passed by urination. This external technique is called extracorporeal shock-wave **lithotripsy** (ESWL).

For large stones in the kidney, a procedure called percutaneous nephrolithomy may be used. In this procedure, the surgeon makes a small incision in the back over the kidney. An instrument called a nephroscope is inserted through the incision into the kidney. The surgeon uses the nephroscope to locate and remove the stone. If the stone is very large, it may be broken up into smaller pieces by an ultrasonic or other kind of probe before removal.

Prognosis

As many as 50% of patients who have had surgical treatment for a kidney stone will have another stone within five years if no medicines are used to treat this condition.

Prevention

Cystinuria is a genetic disorder that currently cannot be prevented.

Dominic De Bellis, PhD

Cystitis

Definition

Cystitis is defined as inflammation of the urinary bladder. **Urethritis** is an inflammation of the urethra, which is the passageway that connects the bladder with the exterior of the body. Sometimes cystitis and urethritis are referred to collectively as a lower **urinary tract infection**, or UTI. Infection of the upper urinary tract involves the spread of bacteria to the kidney and is called **pyelonephritis**.

Description

The frequency of bladder infections in humans varies significantly according to age and sex. The male/female ratio of UTIs in children younger than 12 months is 4:1 because of the high rate of **birth defects** in the urinary tract of male infants. In adult life, the male/female ratio of UTIs is 1:50. After age 50, however, the incidence among males increases due to prostate disorders.

Cystitis in women

Cystitis is a common female problem. It is estimated that 50% of adult women experience at least one episode of dysuria (painful urination); half of these patients have a bacterial UTI. Between 2–5% of women's visits to primary care doctors are for UTI symptoms. About 90% of UTIs in women are uncomplicated but recurrent.

Cystitis in men

UTIs are uncommon in younger and middle-aged men, but may occur as complications of bacterial infections of the kidney or prostate gland.

Cystitis in children

In children, cystitis often is caused by congenital abnormalities (present at birth) of the urinary tract. **Vesicoureteral reflux** is a condition in which the child cannot completely empty the bladder. It allows urine to remain in or flow backward (reflux) into the partially empty bladder.

Causes and symptoms

The causes of cystitis vary according to sex because of the differences in anatomical structure of the urinary tract.

Females

Most bladder infections in women are so-called ascending infections, which means they are caused by disease agents traveling upward through the urethra to the bladder. The relative shortness of the female urethra (1.2–2 in. [3–5 cm] in length) makes it easy for bacteria to gain entry to the bladder and multiply. The most common bacteria associated with UTIs in women include *Escherichia coli* (about 80% of cases), *Staphylococcus saprophyticus*, *Klebsiella*, *Enterobacter*, and *Proteus* species. Risk factors for UTIs in women include:

- Sexual intercourse. The risk of infection increases if the woman has multiple partners.
- Use of a diaphragm for contraception
- An abnormally short urethra
- Diabetes or chronic dehydration
- The absence of a specific enzyme (fucosyltransferase) in vaginal secretions. The lack of this enzyme makes it easier for the vagina to harbor bacteria that cause UTIs.
- Inadequate personal hygiene. Bacteria from fecal matter or vaginal discharges can enter the female urethra because its opening is very close to the vagina and anus.
- History of previous UTIs. About 80% of women with cystitis develop recurrences within two years.

The early symptoms of cystitis in women are dysuria, or **pain** on urination; urgency, or a sudden strong desire to urinate; and increased frequency of urination. About 50% of female patients experience **fever**, pain in the lower back or flanks, **nausea and vomiting**, or shaking chills. These symptoms indicate pyelonephritis, or spread of the infection to the upper urinary tract.

WWW.BOOKBAZ.IR

Males

Most UTIs in adult males are complications of kidney or prostate infections. They usually are associated with a tumor or **kidney stones** that block the flow of urine and often are persistent infections caused by drug-resistant organisms. UTIs in men are most likely to be caused by *E. coli* or another gram-negative bacterium. *S. saprophyticus*, which is the second most common cause of UTIs in women, rarely causes infections in men. Risk factors for UTIs in men include:

- Lack of circumcision. The foreskin can harbor bacteria that cause UTIs.
- Urinary catheterization. The longer the period of catheterization, the higher the risk of UTIs.

The symptoms of cystitis and pyelonephritis in men are the same as in women.

Hemorrhagic cystitis

Hemorrhagic cystitis, which is marked by large quantities of blood in the urine, is caused by an acute bacterial infection of the bladder. In some cases, hemorrhagic cystitis is a side effect of **radiation therapy** or treatment with cyclophosphamide. Hemorrhagic cystitis in children is associated with adenovirus type 11.

Diagnosis

When cystitis is suspected, the doctor will first examine the patient's abdomen and lower back, to evaluate unusual enlargements of the kidneys or swelling of the bladder. In small children, the doctor will check for fever, abdominal masses, and a swollen bladder.

The next step in diagnosis is collection of a urine sample. The procedure differs somewhat for women and men. Laboratory testing of urine samples now can be performed with dipsticks that indicate immune system responses to infection, as well as with microscopic analysis of samples. Normal human urine is sterile. The presence of bacteria or pus in the urine usually indicates infection. The presence of hematuria, or blood in the urine, may indicate acute UTIs, **kidney disease**, kidney stones, inflammation of the prostate (in men), **endometriosis** (in women), or cancer of the urinary tract. In some cases, blood in the urine results from athletic training, particularly in runners.

Females

Female patients often require a pelvic examination as part of the diagnostic workup for bladder infections. Normally, however, a midstream urine sample of 200 mL is collected to test for infection.

A count of more than 104 bacteria CFU/mL (colony forming units per milliliter) in the midstream sample indicates a bladder or kidney infection. A colony is a large number of microorganisms that grow from a single cell within a substance called a culture. A bacterial count can be given in CFU or (colony forming units).

In recent years, many health providers and insurance companies have adopted telephone treatment of women with presumed cystitis. Trained nurses diagnose uncomplicated bladder infections over the telephone based on the patient's symptoms and a series of questions prepared by physicians. The practice has been found safe and cost-effective.

Males

In male patients, the doctor will cleanse the opening to the urethra with an antiseptic before collecting the urine sample. The first 10 mL of specimen are collected separately. The patient then voids a midstream sample of 200 mL. Following the second sample, the doctor will massage the patient's prostate and collect several drops of prostatic fluid. The patient then voids a third urine specimen for prostatic culture.

A high bacterial count in the first urine specimen or the prostatic specimens indicates urethritis or prostate infections respectively. A bacterial count greater than 100,000 bacteria CFU/mL in the midstream sample suggests a bladder or kidney infection.

Other tests

Women with recurrent UTIs can be given **ultrasound** exams of the kidneys and bladder together with a voiding cystourethrogram to test for structural abnormalities. (A cystourethrogram is an x-ray test in which an iodine dye is used to better view the urinary bladder and urethra.) Voiding cystourethrograms are also used to evaluate children with UTIs. In some cases, **computed tomography scans** (CT scans) can be used to evaluate patients for possible cancers in the urinary tract.

Treatment

Medications

Uncomplicated cystitis is treated with **antibiotics**. These include penicillin, ampicillin, and amoxicillin; sulfisoxazole or sulfamethoxazole; trimethoprim; nitrofurantoin; **cephalosporins**; or **fluoroquinolones**. (Flouroquinolones generally are not used in children under 18 years of age.) A 2003 study showed that fluoroquinolone was preferred over amoxicillin,

however, for uncomplicated cystitis in young women. Treatment for women is short-term; most patients respond within three days. Men do not respond as well to short-term treatment and require seven to 10 days of oral antibiotics for uncomplicated UTIs.

Patients of either sex may be given phenazopyridine or flavoxate to relieve painful urination.

Trimethoprim and nitrofurantoin are preferred for treating recurrent UTIs in women.

Over 50% of older men with UTIs also suffer from infection of the prostate gland. Some antibiotics, including amoxicillin and the cephalosporins, do not affect the prostate gland. Fluoroquinolone antibiotics or trimethoprim are the drugs of choice for these patients.

Patients with pyelonephritis can be treated with oral antibiotics or intramuscular doses of cephalosporins. Medications are given for 10–14 days, and sometimes longer. If the patient requires hospitalization because of high fever and **dehydration** caused by **vomiting**, antibiotics can be given intravenously.

Surgery

A minority of women with complicated UTIs may require surgical treatment to prevent recurrent infections. Surgery also is used to treat reflux problems (movement of the urine backward) or other structural abnormalities in children and anatomical abnormalities in adult males.

Alternatives

Alternative treatment for cystitis may emphasize eliminating all sugar from the diet and drinking lots of water. Drinking unsweetened cranberry juice not only adds fluid, but also is thought to help prevent cystitis by making it more difficult for bacteria to cling to the bladder wall. A variety of herbal therapies also are recommended. Generally, the recommended herbs are antimicrobials, such as garlic (*Allium sativum*), goldenseal (*Hydrastis canadensis*), and bearberry (*Arctostaphylos uva-ursi*), and/or demulcents that soothe and coat the urinary tract, including corn silk and marsh mallow (*Althaea officinalis*).

Homeopathic medicine also can be effective in treating cystitis. Choosing the correct remedy based on the individual's symptoms is always key to the success of this type of treatment. **Acupuncture** and Chinese traditional herbal medicine can also be helpful in treating acute and chronic cases of cystitis.

KEY TERMS

Bacteriuria—The presence of bacteria in the urine.

Dysuria—Painful or difficult urination.

Hematuria—The presence of blood in the urine.

Pyelonephritis—Bacterial inflammation of the upper urinary tract.

Urethritis—Inflammation of the urethra, which is the passage through which the urine moves from the bladder to the outside of the body.

Prognosis

Females

The prognosis for recovery from uncomplicated cystitis is excellent.

Males

The prognosis for recovery from uncomplicated UTIs is excellent; however, complicated UTIs in males are difficult to treat because they often involve bacteria that are resistant to commonly used antibiotics.

Prevention

Females

Women with two or more UTIs within a six-month period sometimes are given prophylactic treatment, usually nitrofurantoin or trimethoprim for three to six months. In some cases the patient is advised to take an antibiotic tablet following sexual intercourse.

Other preventive measures for women include:

- drinking large amounts of fluid
- voiding frequently, particularly after intercourse
- proper cleansing of the area around the urethra

In recent clinical trials in humans, a possible vaccine for recurrent urinary tract infections was being tested. The vaccine was administered via a vaginal suppository.

Males

The primary preventive measure for males is prompt treatment of prostate infections. Chronic **prostatitis** may go unnoticed, but can trigger recurrent UTIs. In addition, males who require temporary catheterization following surgery can be given antibiotics to lower the risk of UTIs.

Cystometry

Definition

Cystometry is a test of bladder function in which pressure and volume of fluid in the bladder is measured during filling, storage, and voiding.

Purpose

The urinary bladder stores urine produced by the kidneys. The main muscle of the bladder wall, the detrusor, relaxes to allow expansion of the bladder during filling. The urethra, the tube through which urine exits, is held closed by a ring of muscle, known as the urethral sphincter. As volume increases, stretching of the detrusor and pressure on the sphincter sends signals to the brain, indicating the need for urination, or voiding. Voluntary relaxation of the sphincter and automatic contractions of the detrusor allow successful and virtually complete voiding.

A cystometry study is performed to diagnose problems with urination, including incontinence, urinary retention, and recurrent urinary tract infections. Urinary difficulties may occur because of weak or hyperactive sphincter or detrusor, or incoordination of their two activities. Infection of the bladder or urethra may cause incontinence, as can obstruction of the urethra from scar tissue, prostate enlargement, or other benign or cancerous growths. Loss of sensation due to nerve damage can lead to chronic overfilling.

Precautions

The mild irritation of the urinary tract necessary for insertion of the catheter may occasionally cause flushing, sweating, and nausea.

Description

The patient begins by emptying the bladder as much as possible. A thin plastic catheter is then slowly inserted into the urethra until it reaches the bladder. Measurements are taken of the residual urine volume and bladder pressure. Pressure measurements may require a rectal probe to account for the contribution of the abdominal muscles to the pressure recording.

The bladder is then gradually filled with either warm water, room temperature water, saline solution, carbon dioxide gas, or a contrast solution for x-ray analysis, depending on the type of study being done. The patient is asked to describe sensations during filling, including temperature sensations and when the first feeling of bladder fullness occurs. Once the bladder is completely full, the patient is asked to begin voiding, and measurements are again made of pressure and volume, as well as flow rate and pressure.

Preparation

There is no special preparation needed for this test. The patient may be asked to stop taking certain medications in advance of the test, including sedatives, cholinergics, and anticholinergics.

Aftercare

Cystometry can be somewhat uncomfortable. The patient may wish to reserve an hour or so afterward to recover. Urinary frequency or urgency, and some reddening of the urine, may last for a day. Increasing fluid intake helps to flush out the bladder, but caffeinated, carbonated, or alcoholic beverages are discouraged, because they may irritate the bladder lining. Signs of infection, such as **fever**, chills, **low back pain**, or persistent blood in the urine, should be reported to the examining physician.

Risks

There is a slight risk of infection due to tearing of the urethral lining.

Results

The normal bladder should not begin contractions during filling and should initially expand without resistance. A feeling of fullness occurs with a volume of 100–200 mL. The adult bladder capacity is 300–500 mL. The sphincter should relax and open when the

KEY TERMS

Detrusor—Muscle of the bladder wall.

Sphincter—Ring of muscle between the bladder and the urethra that functions to close off the urethra.

Urethra—Tube that empties urine from the bladder to the exterior of the body.

patient wills it, accompanied by detrusor contractions. During voiding, detrusor contraction should be smooth and lead to a steady urine stream.

Abnormal results

Inability of the bladder to relax during filling, or low bladder volume, may indicate interstitial **cystitis**, prostate enlargement, or **bladder cancer**. Contraction of the bladder during filling may be due to irritation from infection or cysts, obstruction of the bladder outlet, or neurological disease such as **stroke**, **multiple sclerosis**, or **spinal cord injury**. Diminished sensation may occur with nerve lesions, **peripheral neuropathy**, or chronic overfilling.

Cystoscopy

Definition

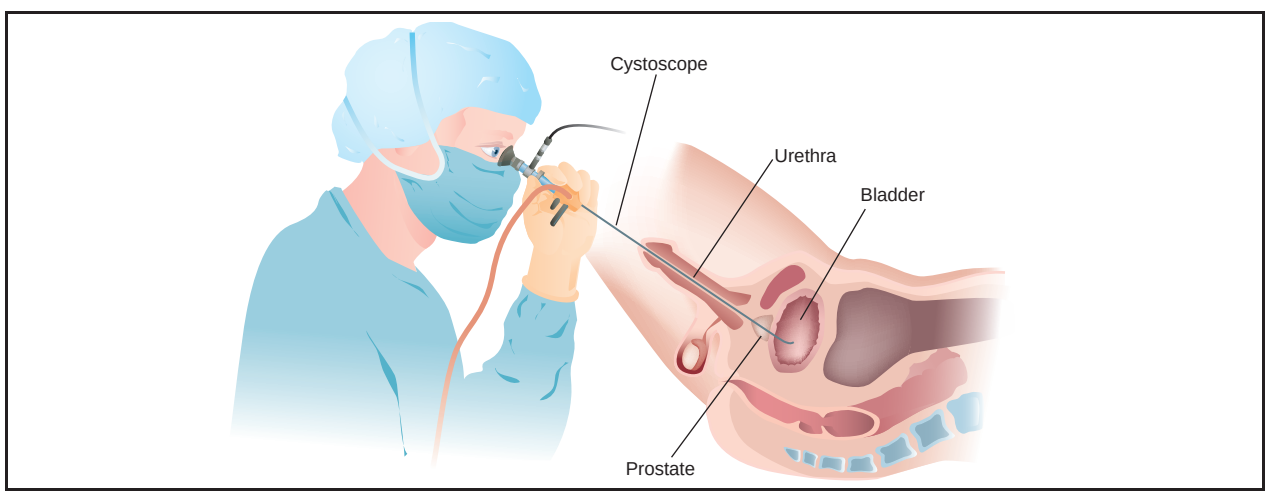
Cystoscopy (cystourethroscopy) is a diagnostic procedure that uses a cystoscope, which is an endoscope especially designed for urological use to examine the bladder, lower urinary tract, and prostate gland. It can also be used to collect urine samples, perform biopsies, and remove small stones.

Purpose

Cystoscopy is performed by urologists to examine the entire bladder lining and take biopsies of any questionable areas. Cystoscopy may be prescribed for patients who display the following conditions:

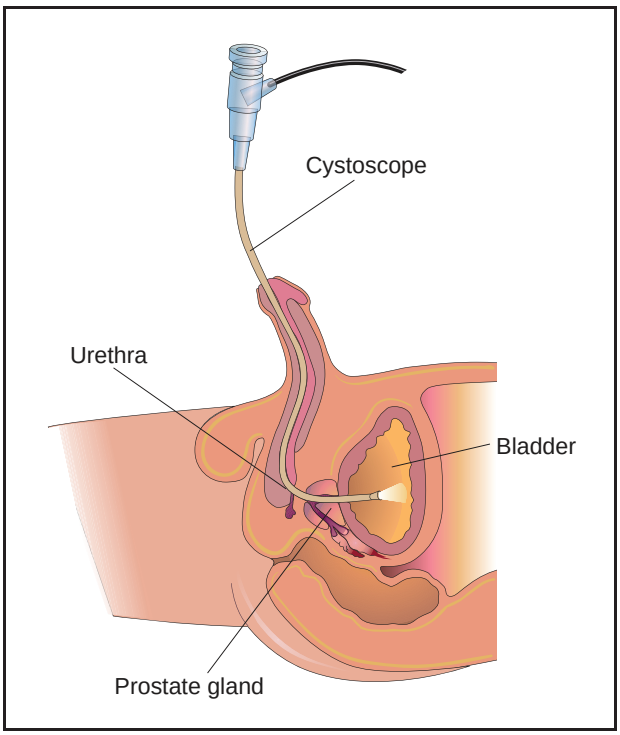
- blood in the urine (hematuria)
- inability to control urination (incontinence)
- urinary tract infection (UTI)
- signs of congenital abnormalities in the urinary tract
- suspected tumors in the bladder
- bladder or kidney stones
- signs or symptoms of an enlarged prostate
- pain or difficulty urinating (dysuria)
- disorders of or injuries to the urinary tract
- symptoms of interstitial cystitis

Blood and urine studies, in addition to x rays of the kidneys, ureters, and bladder, may be performed before a cystoscopy to obtain as much diagnostic information as possible. During the cystoscopy, a retrograde pyelogram may also be performed to examine the kidneys and ureters.



A cystoscope helps the doctor examine the urethra, bladder, and prostate. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

WWW.BOOKBAZ.IR



Cystoscopy is a diagnostic procedure which is used to view the bladder, collect urine samples, and examine the prostate gland. This procedure also enables biopsies to be taken. The primary instrument used in cystoscopy is the cystoscope, a tube which is inserted through the penis into the urethra, and ultimately into the bladder. *(Illustration by Electronic Illustrators Group. Reproduced by permission of Gale, a part of Cengage Learning.)*

Description

There are two types of cystoscopes used to carry out the procedure, a rigid type and a flexible type. Both types are used for the same purposes and differ only in their method of insertion. The rigid type requires that the patient adopt the lithotomy position, meaning that the patient lies on his or her back with knees up and apart. The flexible cystoscope does not require the lithotomy position.

A cystoscopy typically lasts 10–40 minutes. The patient is asked to urinate before surgery and advised that relaxing pelvic muscles will help make this part of the procedure easier. A well-lubricated flexible or rigid cystoscope (urethroscope) is passed through the urethra into the bladder where a urine sample is taken. There may be some discomfort as the instrument is inserted. Fluid is then injected to inflate the bladder and allow the urologist to examine the entire bladder wall. The cystoscope uses a lighted tip for guidance and enables biopsies to be taken or small stones to be removed through a hollow channel in the cystoscope.

During a cystoscopy, the urologist may remove **bladder stones** or **kidney stones**, gather tissue samples, and perform x-ray studies. To remove stones, an instrument that looks like a tiny basket or grasper is inserted through the cystoscope so that small stones can be extracted through the scope's channel. For a biopsy, special forceps are inserted through the cystoscope to pinch off a tissue sample. Alternatively, a small brush-like instrument may be inserted to scrape off some tissue. To perform x-ray studies such as a retrograde pyelogram, a dye is injected into the ureter by way of a catheter passed through the cystoscope. After completion of all required tests, the cystoscope is removed.

Preparation

Before cytoscopy, patients may be asked to give a urine sample to check for infection and to avoid urinating for an hour before the procedure. A sedative may be given about one hour prior to the operation to help the patient relax. The region of the urethra is cleansed and a local anesthetic is applied. Spinal or general **anesthesia** may also be used for the procedure. Distension of the bladder with fluid is particularly painful, and if it needs to be done, as in the case of evaluating interstitial **cystitis**, general anesthesia is required. A signed consent form is necessary for this procedure.

Aftercare

After removal of the cystoscope, the urethra is usually sore, and patients should expect to feel a burning sensation while urinating for one or two days following the procedure. To alleviate discomfort or **pain**, patients may be prescribed pain medication, and **antibiotics** may also be required to prevent infection. Minor pain may also be treated with over-the-counter, nonprescription drugs such as **acetaminophen**. To relieve discomfort, patients may be advised to drink two 8-oz glasses of water each hour for two hours and to take a warm bath to relieve the burning feeling. If not able to bathe, they may be advised to hold a warm, damp washcloth over the urethral opening.

Patients who have undergone a cystoscopy are instructed to:

- take warm baths to relieve pain
- rest and refrain from driving for several days, especially if general anesthesia was used
- expect any blood in the urine to clear up in one to two days
- avoid strenuous exercise during recovery
- postpone sexual relations until the urologist determines that healing is complete

KEY TERMS

Anesthetic—A drug that causes loss of sensation. It is used to lessen the pain of surgery and other medical procedures.

Bladder—The bladder is located in the lower part of the abdomen; it is a structure like a small balloon that collects urine for temporary storage and is emptied from time to time by urinating.

Catheter—A tubular, flexible surgical instrument for withdrawing fluids from (or introducing fluids into) a body cavity, especially one for introduction into the bladder through the urethra for the withdrawal of urine.

Cystoscope—Endoscope especially designed for urological use to examine the bladder, lower urinary tract, and prostate gland.

Diverticula—A pouch or sac occurring normally or from a herniation or defect in a membrane.

Endoscope—A highly flexible, thin viewing instrument used to see inside body cavities.

Endoscopy—A minimally invasive procedure that involves examination of body organs or cavities using an endoscope.

Interstitial cystitis—A chronic inflammatory condition of the bladder involving symptoms of bladder pain, frequent urination, and burning during urination.

Retrograde pyelogram—A pyelography or x-ray technique in which a dye is injected into the kidneys through the ureters.

Ureter—The tube that carries urine from each kidney to the bladder.

Urethra—The tube that carries urine from the bladder to outside the body. In females, the urethral opening is between the vagina and clitoris; in males, the urethra travels through the penis, opening at the tip.

Urogynecologist—A physician that specializes in female medical conditions concerning the urinary and reproductive systems.

Uroradiologist—A radiologist that specializes in diagnostic imaging of the urinary tract and kidneys.

Risks

As with any surgical procedure, there are some risks involved with a cystoscopy. Complications may include profuse bleeding, a damaged urethra, a perforated bladder, a **urinary tract infection**, or an injured penis.

Patients should contact their physician if they experience any of the following symptoms after the procedure, including pain, redness, swelling, drainage, or bleeding from the surgical site; signs of generalized infection, which may include **headache**, muscle aches, **dizziness**, or an overall ill feeling and **fever**; nausea or **vomiting**; or difficult or painful urination.

Cystoscopy is a commonly performed procedure, but it is an invasive technique that involves small yet significant risk. If anesthesia is required, there is additional risk, particularly for people who are obese, smoke, or are in poor health. Those undergoing anesthesia must inform the doctor of any medications they are taking.

Results

A successful cystoscopy includes a thorough examination of the bladder and collection of urine samples for cultures. If no abnormalities are seen, the results are indicated as normal. In this case, the bladder wall appears smooth and the bladder is seen to be of normal size, shape, and position, without obstructions, growths, or stones.

The treating physician can tell the patient what was seen inside the bladder right after the procedure. If a biopsy sample was taken, this will take several days to be examined and tested.

Cystoscopy allows the urologist to detect inflammation of the bladder lining, prostatic enlargement, or tumors. If these are seen, further evaluation or biopsies may be needed. Cystoscopy with bladder distention can also evaluate interstitial cystitis. Bladder stones, urethral strictures, diverticula, or congenital abnormalities can also be detected.

Alternatives

There are procedures that can provide some information about the lining of the bladder, for example, x rays; however, none of these provide as much information to the doctor as a cystoscopy.

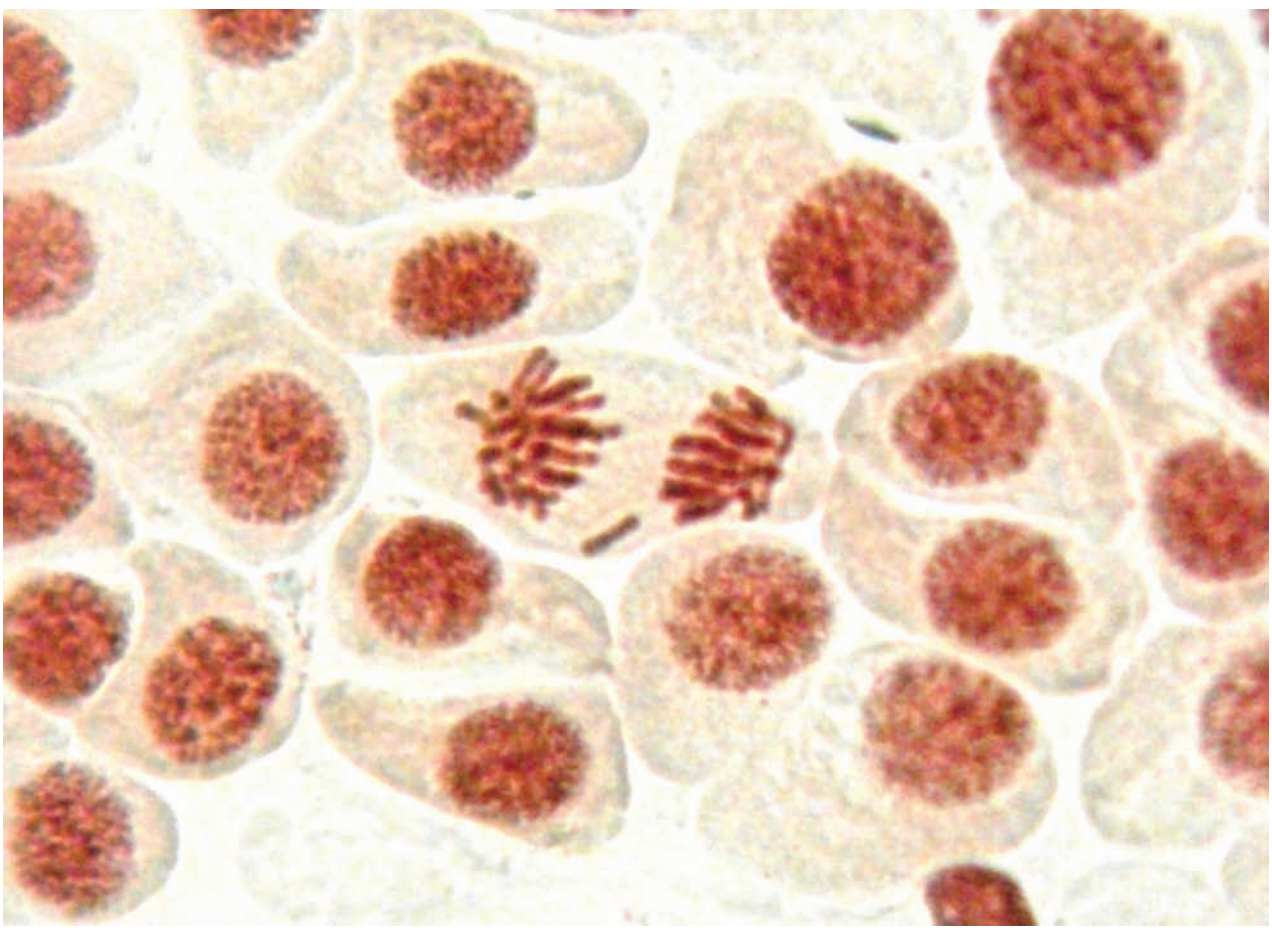
Cytology

Definition

Cytology is the examination of individual cells and small clusters of cells. It may be used for the diagnosis and screening of diseases, including cancers. Cytology also refers to the study of diseases at the



Cancer under a microscope. *(© Dimarion/Shutterstock.com.)*

cellular level. For diagnosing diseases such as cancer, cytology may be referred to as cytopathology.

Purpose

Diagnostic tests are used to detect a disease in individuals who have signs, symptoms, or some other abnormality. A screening test identifies those who might have a certain disease, sometimes before they develop any symptoms, but does not absolutely prove the disease is present. If a screening test is positive, a diagnostic test can be used as a follow-up measure to verify the diagnosis.

Description

Samples for cytology can be obtained in more than one way:

- Fine-needle aspiration (FNA) is a type of biopsy in which tumor samples are taken through thin needles.
- Scrape or brush cytology is a technique in which cells are scraped or brushed from the organ or tissue being tested. Samples from the esophagus, stomach, bronchi (breathing tubes that lead to the lungs), mouth, and cervix (Pap smear) can be obtained using this type of procedure.
- Liquid-based cytology has been introduced in Great Britain as an alternative to the scrape method for collecting cervical cells for Pap smears. It is considered more comfortable and as effective as the Pap test.

How a cytology sample is processed depends on what type of sample it is. A doctor can smear a sample directly on a glass microscope slide. The slide is then stained and viewed by a cytopathologist. In other cases, the fluid is concentrated before being smeared and stained on a slide. This is especially useful for dilute samples, such as those from body cavities.

Precautions

Procedures to gather cells for cytology are often less invasive than other forms of biopsy, and therefore may cause less discomfort, be less likely to result in serious complications, and cost less to perform. In some situations, however, where a piece of tissue is removed rather than individual cells, a different type of biopsy may be required to confirm the cytologic diagnosis.

KEY TERMS

Biopsy—Removing tissue from living patients for a diagnostic examination.

Cytopathology—Another name for cytology; the study of cells or cell types.

Fine-needle aspiration—Removal of tissue or suspensions of cells using a small needle.

Pap smear—A common cytology test used to screen for malignant and premalignant changes of the cervix.

Results

A cytopathologist examines the cells through a microscope and identifies the normal and abnormal cells on the slide using a microscope. Most routine cytology results are available one or two days after the sample is received in the laboratory. Normal results generally indicate no sign of cancer; abnormal cells may show signs that indicate a possible diagnosis of cancer.

Cytomegalovirus antibody screening test

Definition

Cytomegalovirus (CMV) is a common human herpes virus. Detected by a blood test, antibodies to CMV are evidence of a current or past infection.

Purpose

Transmission of the virus can occur by coming into direct contact with oral, respiratory, or genital secretions of a person infected with the virus. Consequences of a CMV infection can be devastating in a pregnant woman; a patient who has recently undergone an organ, bone marrow, or stem cell transplant; or a person with human **immunodeficiency** virus (HIV). Blood products that are to be transfused to persons in these high risk groups should be screened for CMV antibodies. Antibody screening helps control the infection risk for these groups.

In a healthy, nonpregnant person, CMV infection is almost never serious. Symptoms, if present, are mild, often resembling **infectious mononucleosis** due to **Epstein-Barr virus**. Antibody screening distinguishes between these two infections.

Description

When first exposed to CMV, a person's immune system is triggered and quickly makes antibodies to fight the virus. Antibodies are special proteins designed to attack and destroy foreign material, in this case, the cytomegalovirus.

The test combines a person's serum with a substance to which CMV antibodies attach. This antibody-antigen complex is measured and the amount of original antibody determined. If positive for antibodies, the serum is diluted, or titered, and the test repeated until the serum is so dilute it no longer gives a positive result. The last dilution that gives a positive result is the titer reported.

A test positive for CMV antibodies means the person has been infected with the virus, either currently or in the past; it does not mean the person has lifetime immunity. After an infection, this virus, like all members of the herpes virus group, can stay hidden inside a person and cause infection if the person's immune system later weakens and antibody protection decreases. In fact, reactivation of such hidden (or latent) infection is not at all uncommon and usually occurs without symptoms.

Transplant patients and people with weakened immune systems, including those with HIV, are vulnerable to infection from several routes, including from another person, from a donated organ or transfused blood, or from reactivation of a past infection. Before transplant, both the recipient and donor are usually tested for antibodies. A recipient who has never had CMV (negative for antibodies), should not receive an organ from a donor who has had CMV (positive for antibodies). CVM infection can be associated with organ rejection, or can cause illness such as **pneumonia**, hepatitis, or death. Similarly, blood is usually screened for CMV antibodies before being transfused into a person with a weakened immune system.

CMV infection is the most common congenital infection (existing at birth). The infection, passed from mother to baby, can cause permanent mental or physical damage, or death. The antibody screening test tells a woman whether or not she has antibody protection against the virus in case she is exposed during **pregnancy**. Pregnant women 25 years and older who are immune to CMV are much less likely to pass the virus to their babies than younger women who have never been exposed to CMV.

Tests that measure a specific type of antibody help tell the difference between a current and a past infection. Immunoglobulin M (IgM) antibodies appear at the beginning of an infection and last only weeks. Immunoglobulin G (IgG) antibodies appear 10–14 days later and can last a lifetime. A person suspected of having a current infection should be tested at the beginning of the infection and again 10–14 days later.

The CMV antibody screening test is also called the transplant reaction screening test. Results are usually available the following day.

A newer test, the anti-CMV immediate early antigen monoclonal test, can detect CMV infection as early as three hours after infection.

It may be possible to test fetal blood for certain antibodies to CMV virus by drawing a blood sample from the umbilical cord. This may be an important test to add to prenatal care, since newborn babies with CMV often show no symptoms.

Preparation

The adult CMV antibody screening test requires 1 mL of blood. Collection of the sample takes only a few minutes.

KEY TERMS

Antibody—A special protein built by the body as a defense against foreign material entering the body.

Cytomegalovirus (CMV)—A common human virus causing mild or no symptoms in healthy people, but permanent damage or death to an infected fetus, a transplant patient, or a person with HIV.

Titer—A dilution of a substance with an exact known amount of fluid. For example, one part of serum diluted with four parts of saline is a titer of 1:4.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Risks

There are no major risks involved with this testing.

Results

Normal results

A person without previous exposure to CMV will test negative.

Abnormal results

The presence of antibodies means the person has been infected with CMV, either now or in the past. An antibody titer at least four times higher at the end of the illness than at the beginning, or the presence of IgM antibodies, indicates a recent or current first time infection.

People with weak immune systems may not generate antibodies against CMV. A current infection in a transplant patient or a person with HIV is confirmed with other tests, such as viral culture.

Cytomegalovirus infection

Definition

Cytomegalovirus (CMV) is a virus related to the group of herpes viruses. Infection with CMV can cause no symptoms, or can be the source of serious illness in people with weakened immune systems. CMV infection is also an important cause of **birth defects**.

Demographics

CMV is an extremely common organism worldwide. It is believed that about 60% of people in the United States have been infected by CMV at some point in their lives. Up to 90% of high risk groups, such as male homosexuals, are thought to be infected with CMV. CMV prevalence increases with age.

Description

CMV is found in almost all of the body's organs. It is also found in body fluids, including semen, saliva, urine, feces, breast milk, blood, and secretions of the cervix (the narrow, lower section of the uterus).

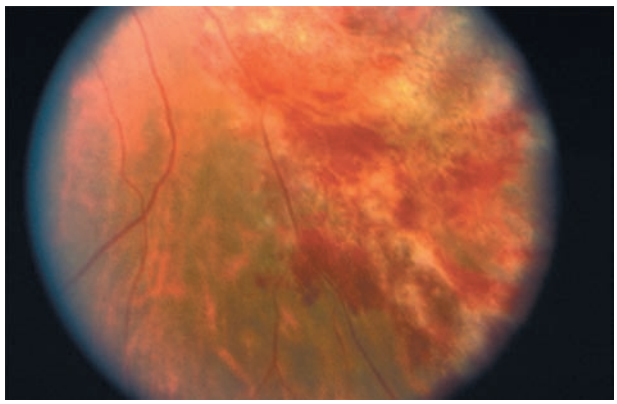
CMV is able to cross the placenta (the organ that provides oxygen and nutrients to the unborn baby in the uterus). Because of this, initial infection in a pregnant woman can lead to infection of the developing baby.

Risk factors

Individuals at high risk for infection with CMV include:

- children who attend day care at day care centers
- individuals who work in day care centers
- patients who receive blood transfusions
- organ transplant or bone marrow transplant patients who receive CMV mismatched organs or bone marrow from donors
- individuals with multiple sexual partners

WWW.BOOKBAZ.IR



An infected retina of an AIDS patient. Cytomegaloviruses are herpes viruses that can, among other problems, act as opportunistic infectious agents in suppressed immune systems, a common problem with AIDS patients. *(Custom Medical Stock Photo, Inc.)*

Causes and symptoms

CMV is passed between people through contact with body fluids. CMV also can be passed through sexual contact. Babies can be born infected with CMV, either becoming infected in the uterus (congenital infection) or during birth (from infected cervical secretions). Congenital infection of CMV causes significant neurological problems and deafness in about 8,000 American newborns every year. The virus can also be spread through blood transfusions and during organ transplants.

Like other herpes viruses, CMV remains inactive (dormant) within the body for life after the initial infection. Some of the more serious types of CMV infections occur in people who have been harboring the dormant virus, only to have it reactivate when their immune system is stressed. Immune systems may be weakened because of treatment with cancerchemotherapy, medications given after organ transplantation, or diseases that significantly lower immune resistance like acquired **immunodeficiency** syndrome (**AIDS**).

In a healthy person, initial CMV infection often occurs without symptoms and is rarely noticed. If symptoms do occur, they typically occur 9–60 days after the first infection. Occasionally, a first-time infection with CMV may cause a mild illness called mononucleosis. Symptoms include **swollen glands**, liver, and spleen; **fever**; increased white blood cells; **headache**; **fatigue**; and **sore throat**. About 8% of all mononucleosis cases are due to CMV infection. A similar infection, though slightly more serious, may occur two to four weeks after receiving a blood **transfusion** containing CMV.

In people with weakened immune systems, CMV infection can cause more serious and potentially life-threatening illnesses. These illnesses include **pneumonia**, and inflammations of the liver (hepatitis), brain (encephalitis), esophagus (esophagitis), large intestine (**colitis**), and retina of the eye (retinitis).

Babies who contract CMV from their mothers during birth rarely develop any illness from these infections. Infants born prematurely who become CMV infected during birth have a greater chance of complications, including pneumonia, hepatitis, decreased blood platelets.
